Abstract. Treeline shifting in tandem with climate change has widely been reported from various parts of the world. In Nepal, several impacts of climate change on the physical environment have been observed, but study on the biological impacts is lacking. This dendrochronological study was carried out at the treeline in the high mountain slope of Kalchuman Lake (3750–4003 m a.s.l.) area of Manaslu Conservation Area in the central Nepal Himalaya to explore the impact of climate change on the treeline dynamic. Two belt transect plots (size: 20 m wide, > 250 m long) were laid which included treeline as well as tree species limit. Ecological mapping of all individuals of dominant trees Abies spectabilis and Betula utilis was done and their tree cores were collected. Stand character and age distribution revealed an occurrence of more matured B. utilis (max. age 198 years) compared to A. spectabilis (max. age 160 years). A. spectabilis contained an overwhelmingly high population (89 %) of younger plants (< 50 years) indicating its high recruitment rate. Population age structure along the elevation gradient revealed an upward shifting of A. spectabilis at the rate of 2.61 m year⁻¹ since AD 1850. The upper distribution limit of B. utilis was found to be stagnant in the past few decades. An increment in plant density as well as upward shifting in the studied treeline ecotones was observed. The temporal growth of A. spectabilis was correlated negatively with the monthly mean and minimum temperature of June to September of the current and previous year. The regeneration of A. spectabilis, on the other hand, was positively correlated with August precipitation and monthly maximum temperature of the month of the current year. The growth and regeneration of A. spectabilis was more sensitive to maximum and minimum temperature rather than average temperature. The growth of the B. utilis was mainly limited by moisture stress during the pre-monsoon season. As these two species presented species-specific responses to climate change with differential pattern in regeneration condition, much wider differences are anticipated in their population status as climate continues to change throughout the century.

1 Introduction

During the past 100 years the global average surface temperature has increased by 0.74 °C ± 0.2 °C, and it is projected to rise by 1.4–5.8 °C by AD 2100 (IPCC, 2007), with the most pronounced and rapid changes at high altitudes and latitudes. However, recent studies have shown spatial and temporal heterogeneity in the past long-term temperature trend (Marcott et al., 2013; PAGES 2k Consortium, 2013). Rapid climate change has many biophysical impacts (IPCC, 2007) and already left several biological fingerprints including change in species composition of ecological communities, range and distribution shift of species as well as changes in phenology of the organisms (Parmesan and Yohe, 2003; Root et al., 2003; Parolo and Rossi, 2008; Chen et al., 2011; Gottfried et al., 2012; Kirdyanov et al., 2012; Pauli et al., 2012; Webb et al., 2012).

The high-altitude limit of forests, commonly known as treeline, timberline or forest line, represents one of the most conspicuous vegetation boundaries (Körner, 1998; Holtmeier, 2009). The position of a treeline is mainly due to strong growth limitation by low-temperature conditions
in Nepal have identified several promising species for dendrochronological study, including *Abies spectabilis* and *Betula utilis* (Bhattarcharya et al., 1992; Cook et al., 2003; Sano et al., 2005; Dawadi et al., 2013), which can grow up to the treeline ecotone (Schickhoff, 2005; Ghimire et al., 2008). Recently, researchers from Nepal have initiated dendroecological studies covering various treeline sites of the Nepal Himalaya (Bhuju et al., 2010; Suwal, 2010; Gaire et al., 2011). However, concrete results on the treeline shifting due to climate change are yet to be explored.

The present study was carried out to (i) ascertain the present position of upper forest, treeline and species limits, (ii) characterize the stand structure and dynamics at the forest line and treeline, and (iii) analyse the response of tree growth and regeneration with climate change using both dendroecological and dendroclimatological techniques. For this study, the treeline is defined as the ecotone up to where 2 m tall trees can be found, and the species limit is defined as the highest position to which seedlings or saplings of the tree species are present. Treeline dynamics describe changes in the regeneration and population dynamics as well as positional change of the tree species in the treeline ecotone.

2 Materials and methods

2.1 Site and species selection

The study was carried out at Manaslu Conservation Area (MCA, area: 1663 km²), a high mountain protected site in the central Nepal Himalaya, established in AD 1998. MCA has a diverse natural resource base with sparse human population and is relatively inaccessible. The area includes nine bioclimatic zones ranging from the lower subtropics to the nival zone with only marginal infrastructure, such as roads. It is the least explored protected area of the country. Local people depend on agriculture, animal husbandry and utilization of natural resources for their sustenance. Buddhism has positively contributed in protecting the forest and biodiversity (Chhetri, 2009).

The study site is a mountain slope adjacent to Kalchuman Lake situated at 3690 m above mean sea level (a.m.s.l.). With human settlements located not more than 2500 m a.m.s.l., the study site is little disturbed anthropogenically. There is a dense forest in between the settlement and study sites. Soil is rich in humus, dark in colour, and its depth varies locally with the steepness of the slope. The tree canopy of the treeline ecotone is formed by *A. spectabilis* and *B. utilis* with a *Rhododendron campulatum* understory and some scattered *Sorbus microphylla*. Above the treeline occur scrubs of *Rhododendron anthropogon* and some herbaceous species. The Himalayan silver fir, *A. spectabilis* is a tall evergreen tree endemic to the Himalaya and found between the lower temperate and lower alpine zone (2400–4400 m) from Afghanistan to Bhutan (Ghimire et al., 2008).
Similarly, *B. utilis* is a medium-sized deciduous tree which forms monospecific as well as mixed forests at the upper limit of the treeline (Ghimire et al., 2008).

The climate of the study area is monsoon dominated. The mean annual rainfall over the past 30 years (1980–2009) at nearby meteorological station at Chame was 967 mm (SD = 280). The monthly average temperature was found to be highest in July and lowest in November (Fig. 1a). The highest recorded temperatures were 23.4 °C during June 1998, the lowest −4.5 °C during January of 1999 and 2000. Over the past 30 years, the station experienced a decreasing trend in rainfall by 3.9 mm year⁻¹ (n = 30, $R^2 = 0.014$, $p < 0.52$) (Fig. 1b) and an increasing trend in mean annual temperature by 0.017 °C year⁻¹ (Fig. 1c). In this station monthly mean minimum temperature was decreasing while monthly mean maximum temperature was increasing significantly (Supplementary Fig. S1). Similarly, mean annual rainfall at Larke, Gorkha, was 1252 mm (SD = 535). In Larke, during the past 30 years (1980–2009) there was a significant ($n = 30$, $R^2 = 0.26$, $p < 0.003$) decreasing trend of rainfall by 28 mm year⁻¹ (Fig. 1b). This decreasing trend is more pronounced and significant ($p < 0.0003$, $R^2 = 0.46$, $n = 23$) after 1987 with a decrease in annual rainfall by 55 mm year⁻¹ between 1987 and 2009.

### 2.2 Field visit and data collection

Field work was carried out in three expeditions: two in 2010 (May–June and September–October) and one in 2012 (October). After careful observation in transect walk at the treeline ecotone, the upper species limits of *A. spectabilis* and *B. utilis* were ascertained. Two altitudinal transect plots (20 m wide and > 250 m long), named Transect 1 (T1) and Transect 2 (T2) were marked at two sites of the treeline ecotone. The plots were oriented with their longer side parallel to the maximum slope and covered the current species limit and treeline ecotone (Fig. 2). T1 was above the continuous forest, while T2 was situated above the middle part of the lake. It was also assumed that the lake might hinder the dispersion of seedlings in the area. Individual plants were categorized and enumerated into three height classes: trees (> 2 m), saplings (0.5–2 m) and seedlings (< 0.5 m), following Wang et al. (2006) and Kullman (2007).

Censuses were carried out inside each plot for *A. spectabilis* and *B. utilis*. For every *A. spectabilis* individual, their geographic location in the plot (latitude, longitude, and altitude); size (diameter at breast height (DBH), height); growth form and internodes interval of all individuals less than 2 m were recorded. The age of trees was calculated by tree core analysis, while that of seedlings and saplings were estimated by counting the branch whorls and scars left along the main stem (Camargo and Gutiérrez, 2004; Wang et al., 2006; Liang et al., 2011). This age estimation was also validated by comparing it with the age obtained by the number of tree rings in the basal sections collected from the root collar of saplings and seedlings ($n = 34$). The age estimates by whorl count and ring count correlated positively ($R^2 = 0.91$, $P < 0.0001$), but the internodes or whorl count ages are systematically lower by 1.57 ± 0.33 years (max. 4 years) in saplings and 1.27 years in seedlings. These suggest that the whorl count method can give a fairly accurate indication of the age of saplings and seedlings of conifer species like *A. spectabilis*.

### 2.3 Tree core and cut-stump collection and analysis

Tree cores were collected using the increment borer (Haglöf, Sweden) following the standard technique suggested by Fritts (1976) and Speer (2010). The cores were collected from the base of each and breast (1.3 m) height of some individuals of *A. spectabilis* and *B. utilis* in the plots. Cores were also collected from the larger *A. spectabilis* and *B. utilis* trees outside of the plots. A total of 249 cores and cut-stump samples (172 *A. spectabilis* and 77 *B. utilis*) were collected (Supplementary Table S1). Collected core and cut-stump samples
The corrected ring-width data were standardized using the computer program ARSTAN (Cook, 1985). The ring-width series were standardized using conventional detrending methods with appropriate options of a negative exponential, linear or cubic spline curve to each series. Each ring-width-index series was then pre-whitened using autoregressive modelling to remove any autocorrelation effects (Cook, 1987). Finally, three chronologies – namely standard, residual and ARSTAN – were prepared using the corrected sample. Various chronology statistics like mean sensitivity, standard deviation, autocorrelation, mean series correlation, signal-to-noise ratio, expressed population signal (EPS) and variance explained were calculated to assess the quality of the site chronologies. Temporal changes in the mean radial growth were assessed by doing regime shift (significant changes in mean radial growth) analysis (Rodionov, 2004). Regime shift was detected based on a statistical test whereby data are processed in time sequence and the hypothesis of a regime shift or discontinuity is tested for each new observation (Rodionov, 2004, 2006). We set the cutoff parameter at 10 years in order to detect changes in mean radial growth driven by high-frequency events and used a 95% level of significance.

2.4 Population demography, regeneration and treeline dynamics

The age obtained from cross-dated samples was used for demographic analysis after the necessary correction for years to core height and years to centre of missed pith. Such correction was made using age–height regression and age–diameter regression combined with the fitting of a circle template to the ring curvature so as to estimate the distance of the core to the centre (Camarero and Gutiérrez, 2004; Speer, 2010). For B. utilis cores from representative sample trees covering different diameter at breast height (DBH) classes were collected. Based on the ages of 39 Betula trees, a regression analysis model between DBH and age was established (Fig. 3), and the relationship was used to estimate the age of all B. utilis trees from which tree cores were not taken. The regeneration rate was determined by age histogram using the number of seedlings, saplings and tree individuals. The treeline dynamics was analysed by density distribution of tree, sapling and seedling as well as the elevation-wise age distribution of the studied species. The upper species limit expansion was studied by observing the age of each individual in the entire plot following Camarero and Gutiérrez (2004) and Liang et al. (2011). In order to calculate the rate of species limit shift, the maximum elevation of live individuals and the position of the oldest individual within each transect was determined. Then, the species limit shift rate (m year$^{-1}$) was calculated by dividing the change in species limit elevation (position) by the time elapsed.
2.5 Climatic influence on radial growth and regeneration

Before proceeding to the response analysis of tree growth and climate, the seasonality of tree growth was defined. Field observation and tree ring data have shown that radial growth of *A. spectabilis* at treeline sites ceases in September–October (Sano et al., 2005). Because climate in the preceding growing season often influences tree growth in the following year (Fritts, 1976), we analysed the influence of temperature and precipitation since June of the previous growth year until October of the current growth year. Simple Pearson correlation coefficients were used to quantify relationships between tree-ring chronologies and climate variables, i.e. monthly average ($T_{\text{mean}}$), maximum ($T_{\text{max}}$) and minimum ($T_{\text{min}}$) temperature and total monthly precipitation. Similarly, influence of seasonal climate on radial growth was also assessed for four seasons – namely winter (December–February, DJF), pre-monsoon (March–May, MAM), monsoon (June–September, JJAS) and post-monsoon (October–November, ON). In addition to this, influence of annual average temperature and total precipitation was also calculated. One of the major difficulties in undertaking dendroclimatic research in Nepal relates to the paucity of long meteorological records for statistically calibrating the tree rings because most of the weather stations in Nepal were only established after 1960 for precipitation and 1970 for temperature (Bhattacharyya et al., 1992; Cook et al., 2003). Available climatic data (1980–2009) of the nearest stations at Chame (28°33′N, 84°14′E and 2680 m a.s.l.) of Manang and Larke Samdo (28°40′N, 84°37′E and 3650 m a.s.l.) of Gorkha were used (Fig. 2). Missing values were replaced by average value of the same month’s data.

To investigate the relationship between regeneration and climate change, recruitment or age data were summed across 5-year intervals as the finest resolution to take into account uncertainties in age estimates and compared with monthly climate records compiled into 5-year averages over the same time period (Camarero and Gutiérrez, 1999; Wang et al., 2006). To describe the climate–recruitment relationships, monthly climatic data (mean, maximum and minimum temperatures, and total precipitation) from Chame, Jagat and Larke stations were used. Climatic factors limiting regeneration were identified from linear correlation analysis between regeneration and climatic data.

3 Results

3.1 Treeline position and structural parameters

The species limit of *A. spectabilis* was recorded at 3984 m (GPS e-Trex) in Transect 1 (T1) and 3955 m in Transect 2 (T2) and its treeline at 3907 m in T1 and 3830 m in T2. In the case of *B. utilis* the treeline and species limit were recorded at the same elevation in both transects, i.e. at 3996 m in T1 and 4003 m in T2.

Structural parameters (age, DBH, and basal area) revealed that both of the species were more matured in T1 than in T2 (Supplementary Table S2). The maximum age of *A. spectabilis* and *B. utilis* was higher in T1 than in T2. *A. spectabilis* tree density ranged from 50 to 280 trees ha$^{-1}$. The total basal area of *B. utilis* in both plots was higher than *A. spectabilis*. The DBH distribution of *A. spectabilis* showed bimodal distribution in T1 with peaks at 0–10 cm and 35–40 cm DBH class (Supplementary Fig. S2). In T2, the DBH distribution of the same species had an inverse-J-shaped distribution indicating continuous regeneration in the area. DBH distribution of *B. utilis* in T1 presents a unimodal bell shape, indicating poor regeneration in recent years. However, DBH distribution of the same species in T2 indicates better recruitment of individuals. Similar trends were observed in height distribution. Age class distribution of the species was heterogeneous with an inverse-J-shaped and unimodal to multimodal bell-shaped distribution (Supplementary Fig. S3).

3.2 Age structure, regeneration and treeline dynamics

The demographic distribution of *A. spectabilis* and *B. utilis* revealed the recruitment and mortality pattern over time (Supplementary Fig. S3 and Fig. 4). The age distribution of *A. spectabilis* indicated that the species was established in the early 1850s in T1 (Fig. 4a) and in the 1950s in T2 (Fig. 4b). The population of *A. spectabilis* was dominated by young individuals comprising 89% of the population below 50 years age. The recruitment of *A. spectabilis* was slow in the 1850s, accelerating after 1950, and again after 1980. This could be related to increased temperature in the area. The recruitment of *B. utilis* started from the 1820s in T1, then reached T2 in the 1840s (Fig. 4a, b). The proportion of young population of *B. utilis* was low (13% of the population < 50 years old) as compared to middle-aged trees (42% being 50–100 years old).
Recruitment of *B. utilis* was lower at the beginning in both transects, but increased slowly to peak in the 1880s in T1 and the 1930s in T2. Regeneration oscillated between the 1880s and 1940s and declined steadily since then.

The comparative age of the two tree species shows that the regeneration of the *B. utilis* was higher before the recruitment of *A. spectabilis* in the treeline community. Spatial–temporal assessment of the upper species limit distribution of *A. spectabilis* and *B. utilis* revealed that the position of *B. utilis* was higher than the position of *A. spectabilis* in both transects (Fig. 4a, b). Similarly, *B. utilis* colonized the area earlier than *A. spectabilis*. Seedlings of the *A. spectabilis* species were found about 80 m higher than trees indicating upward migration (Fig. 4c). Matured trees and young seedlings were mostly dominant at lower elevation indicating stand densification as well. T2 had a lower number of seedlings than T1. Seedlings of *B. utilis* were not recorded in both transects, but some were observed just outside the plots. On the basis of the temporal and spatial distribution of the ages of *B. utilis* at an elevation gradient, we calculated that the seedlings of the species were established at 3860 m between the 1810s and 1820s and at 3990 m during the 1890s (Fig. 4a). The *A. spectabilis* on the other hand made a treeline community around 1850 at 3765 m and reached 3907 m (present *A. spectabilis* treeline) during the 1950s. Seedlings of this species are now established at 3984 m, which is close to the upper limit of *B. utilis*. The average upward movement of the upper distribution limit of *A. spectabilis* at the study sites was calculated to be 2.61 m year\(^{-1}\) (1.56–3.66 m year\(^{-1}\)). The upward shifting of *A. spectabilis* was more pronounced in T2 with migration rate of 3.66 m year\(^{-1}\), while it was 1.56 m year\(^{-1}\) in T1.

The densities of saplings and seedlings of *A. spectabilis* (Supplementary Table S3) indicated that its regeneration was higher in T1 than in T2 and also higher than that of *B. utilis* in both transects. As there was a presence of a large number of saplings and seedlings of *A. spectabilis* in the site but no seedlings of *B. utilis*, it is anticipated that the structure and composition of this treeline community will change in the future.

### 3.3 Tree-ring chronology

A 229-year-long (AD 1782–2010) standard tree ring chronology of *A. spectabilis* was prepared using 46 cores from 29 trees (Fig. 5). The chronology revealed that there was no constant increment in the growth of trees but it fluctuated through time. The years 1818, 1819, 1974 and 1999 were characterized by particularly poor growth, whereas the years 1789, 1814 and 2009 resulted in particularly wide rings. Results of the regime shift analysis suggest that there have been constant changes in mean radial growth which are dominated by short periods of above-average radial growth. Two major periods with low radial growth were 36 years starting in 1854 and 63 years starting in 1940. The period centred on 1905 is one of the shortest with below-average radial growth. In the recent period (after 2000) the radial growth is increased. Several statistics that were calculated for the time span of AD 1782–2010 and for the period of overlap (AD 1920–2005) of all tree-ring series indicated a high dendrochronological potential (Supplementary Table S4).
The radial growth of the Abies spectabilis at the studied treeline was limited by the low temperature with a positive correlation between the ring width chronology and monthly maximum temperature in most of the month and a negative relationship with minimum temperature (Fig. 6a). The radial growth in A. spectabilis correlated negatively with the mean and minimum monthly temperature of June–September \((r > -0.45, P < 0.01)\) months of the current year (Fig. 6a).

However, above-average monthly mean and minimum temperature in the previous year growing period (i.e. June–September) influence negatively the current year growth. Looking at the influence of seasonal climate on the growth, effect of monsoon season (JJAS) temperature on the growth was stronger than individual counterpart months with a significant negative correlation with seasonal mean \((r = -0.58, P < 0.01)\) and minimum \((r = -0.66, P < 0.01)\) temperature.

Though weak, radial growth was negatively correlated with monthly precipitation of most months of the current year (Fig. 6a). The relationship between ring width and precipitation of February of the current year was slightly negative \((r = -0.38, P < 0.05)\). The precipitation during the previous year June correlated positively \((r = 0.45, P < 0.05)\) with current year growth. The correlation between the radial growth and seasonal sum of precipitation was weak and not significant statistically.

Regeneration of the A. spectabilis was favoured positively by the above-average monthly maximum temperature during most of the months and above-average precipitation during dry warm summer months (Fig. 6b). The relationship between regeneration and monthly maximum temperature of the most of the months of the current year was positive and statistically significant \((r > 0.8, P < 0.05)\) while the relationship was negative but significant with the monthly minimum temperature of June–September of the current year \((r > -0.7, P < 0.05)\) (Fig. 6b). The relation...
between regeneration and precipitation in August \((r = 0.96, P < 0.01)\) was positive and statistically significant (Fig. 6b).

It is also evident from Fig. 6a and b that the growth and regeneration of \(A.\) spectabilis is more sensitive to minimum or maximum temperature rather than average temperature because correlation with these is more positive or negative than average.

4 Discussion

4.1 Position, structure and dynamics of treeline

The position and dynamics of the treeline are the result of the interaction of several factors including topoclimate (radiation, temperature, precipitation, length of growing season, and snow cover), topography (slope inclination, relief forms), ecology of tree species (regeneration, seed dispersal, successional stage), site history (climate oscillations, fire, human impact, insect attacks), current biotic (browsing, trampling, diseases and insect pests) and anthropogenic influences (burning, logging, grazing, recreation and tourism) (Holtmeier, 2009). The position of the treeline, species line and species composition varies across the globe as well as at sites within the region (Körner, 1998; Miehe et al., 2007).

In Nepal, the position of the treeline varies between the eastern, central and western region (Schickhoff, 2005). Regardless of the plots, the \(A.\) spectabilis treeline in the present study was found at 3907 m a.s.l. and the \(B.\) utilis treeline at 4003 m a.s.l., which is comparable to the other studies (Körner and Paulsen, 2004; Bhuju et al., 2010; Liang et al., 2014). However, along the western slope of Mt Annapurna, the upper timberline \((B.\) utilis, \(R.\) campanulatum\) at north-facing slopes ascends to 4000–4100 m a.s.l. and to even 4400 m a.s.l. on the Nilgiri northern slope (Schickhoff, 2005). Bhuju et al. (2010) found the treeline at 4050 m a.s.l. in Pangboche of Sagarmatha (Everest) region in eastern Nepal, while at the Lauribina of Langtang in central Nepal it was observed at about 3900 m a.s.l. (Gaire et al., 2011). Generally, the upper treeline elevations in the Hindu Kush–Karakoram–Himalaya (HKH) region increases along two gradients: a NW–SE gradient (corresponding to higher temperature sums at the same elevations along the mountain arc) and a peripheral–central gradient from the Himalayan southern slope to the Great Himalayan range and the Tibetan highlands (related to the combined effects of continentality and mass elevation both leading to higher temperature sums) (Schickhoff, 2005).

The size class distribution of the tree species reflects its regeneration status (Lv and Zhang, 2012). In our study, the structural parameters of the studied species not only varied between the plots but also between the species. Compared to T1, the smaller maximum DBH and younger age of both the \(A.\) spectabilis and \(B.\) utilis in T2 indicated some influence of the Kalchuman Lake in the seed dispersal in the T2 from downside seed source. The DBH class distribution of \(A.\) spectabilis shows a bimodal distribution in T1 with peaks in lower and intermediate DBH classes. The peak in low DBH class indicates that regeneration in recent years is good. The DBH distribution of \(B.\) utilis indicated poor regeneration during recent years. The age distribution was an inverse-J-shaped to multimodal bell-shaped with intra and inter-species differences. Such kind of differences in the age and DBH class distribution of \(A.\) spectabilis and \(B.\) utilis have been observed in the other treeline ecozones of Nepal (Shrestha et al., 2007; Bhuju et al., 2010; Suwal, 2010; Gaire et al., 2011), indicating site- and species-specific regeneration condition in the Nepal Himalaya. Similarly at the \(A.\) spectabilis treeline near the Everest region on the Tibetan side, Lv and Zhang (2012) observed a multimodal age distribution with peaks during 1840–1860 and in recent years. The differential spatio-temporal regeneration pattern reflected in the multimodal size (age and/or DBH) class distributions were also observed in various treeline sites of different mountains: for example \(Picea\) schrenkiana in central Tianshan mountains, NW China (Wang et al., 2006), \(Juniperus\) przewalskii in the Qilian Mountains, NE Tibetan Plateau (Gou et al., 2012), \(Pinus\) cembra in the Pyrenees Mountains, NE Spain (Camarero and Gutiérrez, 2007; Batllori and Gutiérrez, 2008), \(Picea\) glauca in SW Yukon, Canada (Danby and Hik, 2007), \(Larix\) gmelinii in the Putorana Mountains, northern Siberia (Kirdyanov et al., 2012), \(Picea\) glauca, \(Picea\) mariana and \(Larix\) laricina, \(Abies\) lasiocarpa near Churchill, Manitoba, Canada (Mamet and Kershaw, 2012).

Recruitment, critical determinant of the rate of forest or treeline shift (Camarero and Gutiérrez, 2007), has been found to be more sensitive to climate than adult mortality in harsh environments where competition is low, because recruitment has lower climatic thresholds than adult mortality (Lloyd, 1997). The recruitment of \(A.\) spectabilis was high during the 1940–1950s and after the 1980s which might have been facilitated by the warm winter temperature in the area and in the country (Cook et al., 2003; Sano et al., 2005). In the present study, the establishment of \(A.\) spectabilis was high in recent decades as compared to the previous decades, which is consistent to the findings of other studies in the treeline in the Himalaya and other mountains (e.g. Gaire et al., 2011; Batllori and Gutiérrez, 2008; Liang et al., 2011; Lv and Zhang, 2012). Lv and Zhang (2012) found a significant tree recruitment in the recent three decades and sporadic recruitment in earlier periods AD 1760–1960 in the treeline of the Tibetan side of the Everest region. Liang et al. (2011) also found an increased recruitment of Smith fir (\(Abies\) georgei) after the 1950s with an abrupt increase in the 1970s in the Tibetan mountains. Batllori and Gutiérrez (2008) also observed past and recent synchronous recruitment trends of \(Pinus\) cembra with climate change at the treelines in the Iberian eastern range of the Pyrenees.
The regeneration at the treeline can be sporadic or episodic (Cuevas, 2002; Lv and Zhang, 2012). Patchy spatial distribution of A. spectabilis, with gaps in some diameter and age classes observed in the present study, indicates episodic regeneration. The dominance of multimodal age distributions also observed in other alpine or forest–tundra ecotone studies suggested that recruitment in treeline forest ecosystems is episodic or sporadic rather than gradual (Szeicz and MacDonald, 1995; Cuevas, 2002; Batllori and Gutiérrez, 2008; Lv and Zhang, 2012). The spatial distribution of B. utilis was more regular compared to A. spectabilis. In this study, establishment of B. utilis in recent decades has been very poor as compared to previous decades. A similar trend has been reported from other treeline sites (e.g. Bhuju et al., 2010). Recruitment of the species was slow in the beginning in both transects and increased gradually to reach at peak in the 1880s in T1 and the 1930s in T2 with a slight oscillation between the 1880s and 1940s. Similarly, the regeneration of B. utilis before the arrival of A. spectabilis was high. The maximum age of B. utilis was higher than Rhododendron campanulatum (Prabina Rana, personal communication, 2013) and the maximum age of R. campanulatum was higher than that of A. spectabilis. Hence, this area might have been colonized by shade intolerant B. utilis trees followed by shade tolerant understory tree R. campanulatum and was later invaded by A. spectabilis trees.

Seedling establishment is an important factor dictating the altitudinal limits of treeline species (Hughes et al., 2009). Evidently, treeline rise depends on seeds produced at the local treeline rather than propagulae from more distant sources at lower elevations (Kullman, 2007). At and above the treeline in the study site in the Kalchuman Lake area, we observed neither long-living krummholz nor sub-fossil wood of A. spectabilis and B. utilis. Matured and young seedlings of A. spectabilis and matured Betula were mostly dominant in the lower elevation. However, some seedlings of A. spectabilis, probably due to global warming, have been thriving at much higher elevation than tree individuals. This study indicated both stand densification and upward migration as recorded in many other areas (Camarero and Gutiérrez, 2004; Danby and Hik, 2007; Gehrig-Fasel et al., 2007; Kullman et al., 2001, 2002; Kullman and Öberg, 2009; Chauchard et al., 2010; Leonelli et al., 2011; Mamet and Kershaw, 2012; Kirdyanov et al., 2012). Kullman and Öberg (2009) presented a regional-scale treeline rise of Betula pubescens ssp. czerepanovii, Picea abies and Pinus sylvestris in the southern Swedish Scandes of 70–90 m on average with maximum up-shifts of about 200 m since around AD 1915. Danby and Hik (2007) found an increased tree density as well as an advancement of Spruce (Picea glauca) treeline elevation by 65–85 m on south-facing slopes in southwest Yukon, Canada during the early to mid-20th century. Similarly, Kirdyanov et al. (2012) observed an upslope shift of the Larix gmelinii treeline position by approximately 30–50 m in altitude in the Putorana Mountains, northern Siberia during the last century. However, Liang et al. (2011) found no significant upward movement in fir treelines in the Tibetan Plateau despite the warming in the region in the past 200 years.

### 4.2 Climatic factors affecting tree growth and regeneration dynamics

Average upward shifting of the upper distribution limit of A. spectabilis at the treeline ecotone was about 2.61 m year$^{-1}$ with some local variation in the area. This upward migration trend of A. spectabilis is consistent with the upward migration (34 m per decade) of A. spectabilis in the treeline of the Samagaun region of the MCA (Suwal, 2010), and of Pinus wallichiana (19 and 14 m per decade on south- and north-facing slope) in the western Himalayas (Dubey et al., 2003). Several other studies have reported treeline shifting in different regions of the world (e.g. Camarero and Gutiérrez, 2004; Danby and Hik, 2007; Gehrig-Fasel et al., 2007; Harsch et al., 2009; Kullman 2001, 2002; Kullman and Öberg, 2009; Chauchard et al., 2010; Leonelli et al., 2011; Mamet and Kershaw, 2012; Kirdyanov et al., 2012). Kullman and Öberg (2009) presented a regional-scale treeline rise of Betula pubescens ssp. czerepanovii, Picea abies and Pinus sylvestris in the southern Swedish Scandes of 70–90 m on average with maximum up-shifts of about 200 m since around AD 1915. Danby and Hik (2007) found an increased tree density as well as an advancement of Spruce (Picea glauca) treeline elevation by 65–85 m on south-facing slopes in southwest Yukon, Canada during the early to mid-20th century. Similarly, Kirdyanov et al. (2012) observed an upslope shift of the Larix gmelinii treeline position by approximately 30–50 m in altitude in the Putorana Mountains, northern Siberia during the last century. However, Liang et al. (2011) found no significant upward movement in fir treelines in the Tibetan Plateau despite the warming in the region in the past 200 years.

Growth of a tree is associated with several abiotic factors including climate (Fritts, 1976). The radial growth of A. spectabilis fluctuated over time with changing climate and we did not observe constant increment or decrement in the growth. However, a few studies have reported enhanced radial growth of the western Himalayan conifer during recent years (e.g. Borgaonkar et al., 2011). The radial growth of A. spectabilis in the treeline is more responsive to temperature change. Tree growth was positively correlated with temperature ($T_{\text{mean}}$, $T_{\text{max}}$ and $T_{\text{min}}$) from October of the previous year to April of the current year which indicates that temperature before the growing season has a main influence on the radial growth during the subsequent growing period. High winter temperature may induce early melting of snow with the easy availability of melt water for growth in the growing season. Studies also have reported that monthly and seasonal winter temperatures are more limiting than growing-season temperatures to annual radial growth in many upper treeline sites with a positive relationship with winter temperature (Bräuning, 2004; Pederson et al., 2004; Borgaonkar et al., 2011). Bräuning (2004) found a strong positive relationship between the A. spectabilis ring...
width chronology and temperature from November of the previous year to January of the current year in western Nepal. Borgaonkar et al. (2011) found a strong positive relationship between the mean annual and winter (DIF) temperatures of the concurrent year and growth of western Himalayan conifers. The negative relationship, observed in the present study, with the pre-monsoon (MAM) and monsoon season (JJAS) temperature points towards some threshold temperature or moisture stress because increase in temperature in the pre-monsoon and monsoon season without adequate rainfall increases the evapotranspiration which leads to a soil-moisture deficit and limits tree growth (Fritts, 1976; Cook et al., 2003; Yadav et al., 2004). Other studies from the Nepal Himalaya revealed that tree-ring width of *A. spectabilis* is controlled by pre-monsoon (March–May) climate with negative correlation with temperature and positive correlation with precipitation indicating that moisture availability in this season limits tree growth (Cook et al., 2003; Sano et al., 2005; Chhetri and Thapa, 2010; Gaire et al., 2011). Most of these studies were carried out in the areas much lower than treeline ecotone. Similarly, Yadav et al. (2004) obtained a negative as well as weakened relationship between the mean temperature of the summer months and growth of *A. spectabilis* from treeline sites of the western Himalaya. In the present study, responses of radial growth of *A. spectabilis* to minimum and maximum temperatures in the current year were in the opposite direction. This indicated to the prevalence of threshold temperature above or below which the responses become less sensitive to temperature or nonlinear to inverted U-shaped relationship (Paulsen et al., 2000; D’Arrigo et al., 2004; Yadav et al., 2004; Kullman, 2007).

In this study, the radial growth of *A. spectabilis* was less strongly correlated with precipitation, having significant negative correlation only with February precipitation. As precipitation in these months falls in the form of snow, high snow accumulation delays the growth initiation, shortening the growth period and ultimately resulting in the formation of a narrow ring. A deep snow pack in late winter has been shown to effectively reduce radial growth rates by maintaining low soil temperatures and delaying initiation of cambial expansion (Fritts, 1976; Pederson et al., 2004). Above-average moisture during the June of the previous year positively affects the current year’s growth because above-average moisture during summer and early autumn may promote storage of carbohydrates and bud formation, thus enhancing growth during the following year (D’Arrigo et al., 2001; Fritts, 1976). The weak correlation of *A. spectabilis* radial growth with the precipitation also might be due to its sensitivity to temperature compared to precipitation. Conversely the weak correlation could be due to variation in the precipitation between the sampling sites and the local stations because in the Himalaya precipitation fluctuates greatly, even within a small geographic area (Barros et al., 2004).

The relationship between regeneration of *A. spectabilis* and the monthly maximum temperature of January–December of the current year was positive while the relationship was negative with the monthly minimum temperature of the current year, indicating that low temperature adversely affects seedling survival. Severe soil frosts during cold winters were considered to be critical factors in the control of seedling survival by causing needle and shoot desiccation or fine-root mortality (Körner, 2003; Pederson et al., 2004; Kullman, 2007). Since extremely low cool-season temperatures facilitate the formation of abrasive ice crystals that physically damage trees and as a result often limit establishment at the treeline, this research also supports other recent studies documenting the critical impact of warmer winter temperatures on increased tree establishment in the high-elevation ecotones (Kullman, 2007; Kullman and Öberg, 2009; Harsch et al., 2009). The regeneration of *A. spectabilis* was positively correlated with the precipitation of May–August months. The positive relationship with the precipitation of these summer months implies that as the temperature had already attained the minimum threshold required for growth, high rainfall aids the survival and growth of seedlings and saplings. During summer months the temperature in the study area would often be high. So, low rainfall may create a desiccation situation and will have a stronger effect on recruitment because germinants are more sensitive to drought stress (Hughes et al., 2009; Fajardo and McIntire, 2012). Comparing with the past long-term reconstructed climatic data (Cook et al., 2003), the regeneration of *Abies* seems to be good during the episode of warm winter and cool summer. Hence, temperature plays a crucial role in growth and regeneration of *A. spectabilis* at the natural climatic treeline of the Himalaya.

From a similar study at the timberline on the Tibetan side of the Everest region, Lv and Zhang (2012) found that *A. spectabilis* recruitments in 5-year classes were positively correlated with their corresponding monthly mean air temperatures in June and September and with Palmer Drought Severity Index in June. The relationship was inverse for regeneration and ring width. From a study in a treeline on the southeastern Tibetan Plateau, Liang et al. (2011) found a significant positive correlation between the Smith fir (*Abies georgei var. smithii*) recruitment and both summer and winter temperatures. Wang et al. (2006) reported that several consecutive years of high minimum summer temperature and spring precipitation was the main factors favouring the establishment of *Picea schrenkiana* following germination within the treeline ecotone in the central Tianshan mountains.

Due to the lack of young seedlings and saplings as well as long climatic data, we could not calculate the climatic variables limiting growth and regeneration of *B. utilis*. However, in a recent study in birch timberlines from the Nepal Himalaya including our study site, Liang et al. (2014) using CRU grid-based data found a significant positive relationship between tree-ring width chronologies of *B. utilis* and precipitation in May and the pre-monsoon (MAM) season and a less strong negative relationship with temperature. They
concluded that Himalayan birch growth at the upper timberlines is persistently limited by moisture availability during the pre-monsoon season. The poor regeneration and lack of recent shifting of the *B. utilis* in the area might result from the increasing moisture stress (Liang et al., 2014) as available precipitation data from the nearby station have shown a decreasing trend in the precipitation. In addition to the influence of climate change, the lack of recent regeneration of the *B. utilis* seedlings could be due to the influence of increased canopy cover by its own and associated tree species as well as dense shrub scrub because *B. utilis* seedlings could not establish under their own closed canopy even if they produce viable seeds (Shrestha et al., 2007) because the birch seedling growth is facilitated by direct sunlight (Shrestha et al., 2007; Hughes et al., 2009).

### 4.3 Treeline dynamics with climate change

The relationships between regeneration, treeline shifts and climate change may be more complex because climate may affect tree recruitment and treeline advance rate in different ways (Camarero and Gutiérrez, 2004; Wang et al., 2006; Kirdyanov et al., 2012). A treeline ascent implies several consecutive processes: production of viable seeds, dispersal, availability of adequate regeneration sites, germination, seedling survival and persistence until the individual reaches adulthood (Wang et al., 2006; Kullman, 2007). Climate variability affects all these sequential stages, but the same climatic variable can enhance one of these processes while inhibiting another one (Camarero and Gutiérrez, 2004; Wang et al., 2006). At a global scale, treelines are considered to be constrained primarily by growing season temperature (Körner and Paulsen, 2004). However, at many alpine tree-line ecotones, both winter and summer temperatures are often key constraints on tree recruitment (Harsch et al., 2009; Liang et al., 2011) including other local site conditions, species’ traits and feedback effects (Danby and Hik, 2007; Batllori and Gutiérrez, 2008). In the present alpine treeline study the establishment of the *A. spectabilis* is also controlled by both winter and summer climatic events.

An increasing number of studies have demonstrated that tree population density at treelines can respond quickly to rising temperatures (Camarero and Gutiérrez, 2004; Kullman, 2007; Liang et al., 2011) compared to the changes in treeline position because of the great longevity and phenotypic plasticity of tree individuals (MacDonald et al., 1998; Lloyd, 2005). If temperature is the primary and dominant driver for both recruitment and growth, these processes should be positively synchronized (Fajardo and McIntire, 2012). Some previous studies at treelines found concurrent synchronies (MacDonald et al., 1998; Batllori and Gutiérrez, 2008) and lagged synchronies of tree growth and regeneration in both positive and negative directions with climate change (Fajardo and McIntire, 2012). We found a synchronous regeneration of *A. spectabilis* in the treeline ecotone with climate warming. The climatic conditions that enhance radial growth of *A. spectabilis* were almost similar to the climatic conditions that enhance regeneration with slight variation in some months, which is similar to the findings of other studies (Szeicz and MacDonald, 1995; Camarero and Gutiérrez, 1999). In this study both the recruitment and radial growth of *A. spectabilis* was found to be associated positively with winter temperature and negatively with summer (May–August) months’ mean and minimum temperature.

In spite of the regeneration of *A. spectabilis* above the existing treeline, the pace of future treeline shifting with climate change may not necessarily be the same because a seedling takes many years from establishment to reach its tree height (in the treeline, *Abies* took more than 30 years to reach 2 m height) and then to develop into a forest stand (Lloyd, 2005). On the other hand, there are no seedlings of *B. utilis* in and above the treeline. It will take several decades for newly established *Betula* seedlings to develop and form a treeline even if they establish now. As *A. spectabilis* in the treeline is more responsive to temperature change, an advance of this at the natural treeline of the Himalaya with climate change may continue if a long-term warming trend stimulates growth frequently enough even in cooler years or if low temperature events/periods which limit growth and regeneration are insignificant or if there would not be water deficit in plants which could offset the expected positive effects from temperature increase in tree establishment, growth and the upslope advance of treeline (Paulsen et al., 2000; Daniels and Veblen, 2004; Wang et al., 2006; Kullman and Öberg, 2009). In the case of *B. utilis*, Liang et al. (2014) reported that the birch treeline of the Himalaya is a rare case of a drought-induced alpine timberline and Himalayan birch at its upper distribution boundary is increasingly at risk of survival. Therefore, downslope range shift may occur as a response to global-change-type droughts (Liang et al., 2014). With the supportive evidence of differential life history, regeneration condition and the species-specific response of these two treeline species to climate change, it is clear that, in addition to treeline position, the community structure in the studied treeline in the Himalaya is going to change, if current climate change and response pattern continues.

### 5 Conclusions

The present study provided a recruitment pattern and dynamics history of Himalayan fir and Mountain birch at the high-altitude treeline of the Manaslu region, central Nepal Himalaya. Although regeneration patterns varied between the species, increasing trends of stand densification as well as upward shifting of the studied treeline is evident. The upward shift of *A. spectabilis* at MCA was estimated to be 2.61 m year$^{-1}$. In spite of upward migration of *B. utilis* up to the mid-20th century, its upper distribution limit has been stagnant in recent years. The regeneration of *A. spectabilis*...
was positively related with monthly maximum temperature in most of the months of the current year and precipitation in May–August although the growth of the *B. utilis* can be also limited by pre-monsoon precipitation (Liang et al., 2014). Spatial and temporal variations in age structure and regeneration pattern of these two species and their species-specific response to climate indicated that the plant communities at the treeline ecotone in the Nepal Himalaya were sensitive to climate change and the studied treeline is changing. Studies incorporating multiple species and covering other proxy evidence like pollen from lake sediments could enhance our understanding of spatio-temporal treeline and vegetation dynamics in association with climate change.
