Abstract. Recent studies have shown that the Early Eocene Climatic Optimum (EECO) was preceded by a series of short-lived global warming events, known as hyperthermals. Here we present high-resolution benthic stable carbon and oxygen isotope records from ODP Sites 1262 and 1263 (Walvis Ridge, SE Atlantic) between ∼54 and ∼52 million years ago, tightly constraining the character, timing, and magnitude of six prominent hyperthermal events. These events, which include Eocene Thermal Maximum (ETM) 2 and 3, are studied in relation to orbital forcing and long-term trends. Our findings reveal an almost linear relationship between δ¹³C and δ¹⁸O for all these hyperthermals, indicating that the eccentricity-paced covariance between deep-sea temperature changes and extreme perturbations in the exogenic carbon pool persisted during these events towards the onset of the EECO, in accordance with previous observations for the Paleocene Eocene Thermal Maximum (PETM) and ETM2. The covariance of δ¹³C and δ¹⁸O during H₂ and I₂, which are the second pulses of the “paired” hyperthermal events ETM2-H₂ and I₁-I₂, deviates with respect to the other events. We hypothesize that this could relate to a relatively higher contribution of an isotopically heavier source of carbon, such as peat or permafrost, and/or to climate feedbacks/local changes in circulation. Finally, the δ¹⁸O records of the two sites show a systematic offset with on average 0.2 ‰ heavier values for the shallower Site 1263, which we link to a slightly heavier isotopic composition of the intermediate water mass reaching the northeastern flank of the Walvis Ridge compared to that of the deeper northwestern water mass at Site 1262.

1 Introduction

The early Paleogene was characterized by a highly dynamic climatic system both on long (> 10⁶ years) and short (< 10⁴ years) timescales. From the late Paleocene (∼58 Ma) to the early Eocene (∼50 Ma), Earth’s surface experienced a long-term warming trend that culminated in an extended period of extreme warmth, called the Early Eocene Climatic Optimum (EECO; Zachos et al., 2001a, 2008; Bijl et al., 2009; Westerhold and Röhl, 2009). During the EECO, global temperatures reached a long-term maximum lasting about 2 Myr, characterized by the warmest temperatures of the Cenozoic (Zachos et al., 2008). Superimposed on the long-term warming trend were a series of short-lived global warming (hyperthermal) events, accompanied by the release of ¹³C-depleted carbon into the ocean-atmosphere carbon reservoirs (Zachos et al., 2005; Lourens et al., 2005; Nicolò et al., 2007; Littler et al., 2014; Kirtland Turner et al., 2014). These events are of particular interest as they represent useful analogs for the current global warming, despite differences in background climatic conditions and rates of change (e.g., Zachos et al., 2008; Hönisch et al., 2012; Zeebe and Zachos, 2013).

The Paleocene Eocene Thermal Maximum (PETM or ETM₁, ∼56 Ma), lasting less than 200 kyr, was the most extreme of these episodes. During the PETM global temper-
Temperature rose by 5–8 °C, and massive amounts of carbon were released as evidenced by a significant negative carbon isotope excursion (CIE) of > 3 ‰ in the ocean/atmosphere carbon pools, and widespread dissolution of seafloor carbonate (Kennett and Stott, 1991; Dickens et al., 1995; Thomas and Shackleton, 1996; Zachos et al., 2005, 2008; Slijts et al., 2007; McInerney and Wing, 2011). A series of similar events are recorded in carbonate records from marine and continental deposits from the early Paleogene, as expressed by negative excursions in δ13C and δ18O often accompanied by dissolution horizons (e.g., Cramer et al., 2003; Lourens et al., 2005; Agnini et al., 2009; Galeotti et al., 2010; Stap et al., 2010; Zachos et al., 2010; Abels et al., 2012, 2015; Slotnick et al., 2012; Kirtland Turner et al., 2014; Littler et al., 2014). Orbitally tuned records for this geological interval provide evidence that the early Eocene hyperthermal events were paced by variations in the Earth’s orbit, specifically in the long- and short- eccentricity cycles. (e.g., Cramer et al., 2003; Lourens et al., 2005; Littler et al., 2014; Zachos et al., 2010; Sexton et al., 2011).

Several different carbon sources have been proposed to explain the negative CIE, including (1) the release of methane by thermal dissociation of gas hydrates on the continental slopes (Dickens et al., 1995); (2) the burning of peat and coal deposits (Kurtz et al., 2003); and (3) the release of carbon from thawing of permafrost soils at high latitudes as a feedback or as a direct response to orbital forcing (DeConto et al., 2012); while (4) a redistribution of 13C-depleted carbon within oceans has been proposed as a mechanism for hyperthermals in the early to middle Eocene interval (Sexton et al., 2011).

Despite the uncertainty in carbon source and triggering mechanism of the hyperthermal events, a common reservoir has been theorized to explain the consistent covariance in benthic foraminiferal δ13C and δ18O across both the PETM and ETM2, indicating that changes in the exogenic carbon pool were similarly related to warming during these events (Stap et al., 2010). The aim of this paper is to test this relationship by constraining the relative timing and magnitude of changes in deep ocean temperatures and carbon isotope excursions for a series of carbon isotope excursions that succeed ETM2, initially identified by Cramer et al. (2003) in the composite bulk carbonate δ13C record from several deep-sea sites (ODP Sites 690 and 1051; DSDP Site 550 and 577). For this purpose, we generated high-resolution carbon and oxygen stable isotope records of the benthic foraminiferal species *Nuttalides truempyi* from ODP Sites 1262 and 1263 (Walvis Ridge), encompassing the interval from the ETM2 (Stap et al., 2010) to the ETM3 (Röhl et al., 2005), providing the first complete high-resolution benthic stable isotope records for the early Eocene events leading to the onset of the EECO.

**Figure 1.** Paleogeographic reconstruction for the early Eocene (~54 Ma) showing the position of Sites 1263 and 1262 (Walvis Ridge), (map provided by Ocean Drilling Stratigraphic Network, ODSN; http://www.odsn.de/odsn/services/paleomap/paleomap.html, modified). Also shown the locations of ODP Sites 690 and 1051 and DSDP Site 550 and 577 (Cramer et al., 2003) and Mead Stream (Slotnick et al., 2012).

### 2 Materials and methods

#### 2.1 Site location and sampling

ODP Sites 1262 and 1263 represent the deepest and shallowest end-members of a 2 km depth transect recovered during ODP Leg 208. Site 1263 is located just below the crest of the northeast flank of Walvis Ridge, in the southeastern Atlantic, at a water depth of 2717 m, whereas Site 1262 was drilled near the base of the northwestern flank of Walvis Ridge at a water depth of 4759 m (Fig. 1). The estimated paleodepths of Sites 1262 and 1263 at ~ 56 Ma were ~ 3600 and 1500 m, respectively (Zachos et al., 2004). The material recovered at the two sites provided an expanded sequence of early Paleogene sediments, yielding a complete section mainly composed of calcareous nanofossil ooze, chalk and marls. The composite depth scale for Site 1263 was constructed using the magnetic susceptibility (MS) and sediment lightness (L*) from the four holes (Zachos et al., 2004).

Samples were collected at the Bremen Core Repository from Holes A, B and C for Site 1263, and Holes A and B for Site 1262, according to the shipboard meters composite depth section (mcd; Zachos et al., 2004). A 28 m thick interval of Site 1263 was sampled at a resolution of 5 cm from ~ 268 to ~ 296 mcd, and a ~ 6 m interval of Site 1262 was sampled at a resolution of 3 cm from ~ 103 to ~ 109 mcd (Fig. 3). Prior to the analyses, samples were freeze dried, washed and sieved to obtain fractions larger than 38, 63 and 150 µm at the University of California, Santa Cruz and Utrecht University.

#### 2.2 Stable isotopes

Multi-specimen samples of *N. truempyi* were picked from the > 150 µm fraction. The stable isotope values of picked specimens (average of 6–8 foraminiferal calcite tests) from Site...
1263 were carried out at Utrecht University using a CARBO-KIEL automated carbonate preparation device linked on-line to a Thermo-Finnigan MAT253 mass spectrometer. Calibrations to the international standard (NBS-19) and to the in-house standard (Naxos marble) show an analytical precision of 0.03 and 0.08 ‰ for δ^{13}C and δ^{18}O, respectively. The stable isotope values of picked specimens from Site 1262 were analyzed on a KIEL IV carbonate preparation device linked on-line to a Thermo-Finnigan MAT253 mass spectrometer, at the UCSC Stable Isotope Laboratory, Santa Cruz. Calibrations to the in-house standard Carrara marble (CM05) and international standards (NBS-18 and NBS-19) yield an analytical precision of 0.05 and 0.08 ‰, for δ^{13}C and δ^{18}O, respectively. All values are reported in standard delta notation relative to VPDB (Vienna Pee Dee Belemnite). Outliers were defined by adding or subtracting an upper and lower boundary of 2σ from a 13-points moving average, following the method by Liebrand et al. (2011). Published benthic isotope data of the same foraminiferal species were included in this study to obtain longer continuous records of Site 1263 and 1262 (Stap et al., 2010; Littler et al., 2014; Figs. 3 and 4).

### 2.3 Paleotemperature reconstructions

Paleotemperatures were obtained from the benthic foraminiferal δ^{18}O values by applying the equation of Bemis et al. (1998):

\[ T (°C) = 16.9 - 4.38 (δ^{18}O_c - δ^{18}O_{sw}) + 0.10 (δ^{18}O_c - δ^{18}O_{sw})^2. \]

(1)

The temperature scale is computed assuming an ice-free sea water value (δ^{18}O_{sw}) of −1.2 ‰ (VPDB). This value is calculated correcting the estimated deep-sea δ^{18}O_{sw} value of −0.98 ‰ (SMOW) relative to PDB scales by subtracting 0.27 ‰ (Hut, 1987). The N. truempyi δ^{18}O was adjusted for disequilibrium vital effects by adding 0.35 ‰ (Shackleton et al., 1984; Shackleton and Hall, 1997), on the assumption that the isotopic disequilibrium for this species remained constant through time.

### 3 Age model

Given the typical low-resolution age control afforded by magneto- and bio-stratigraphy, and the availability of a robust cycle (i.e., orbital) based chronology for the Leg 208 sites (Westerhold et al., 2007), we developed an eccentricity-tuned age model for the studied interval using the red over green color ratio (a*) records of ODP Sites 1263 and 1262 (Fig. 2). For tuning, we applied first spectral analysis in the depth domain using standard Blackman-Tukey and Gaussian filtering techniques as provided by the AnalySeries program (Paillard et al., 1996). Site 1262, the deepest site at Walvis Ridge, was chosen as the backbone for our tuning. The a* record of this site clearly revealed a ~3 m period, interpreted as reflecting the climatic imprint of the 405 kyr eccentricity cycle (Lourens et al., 2005). Subsequently, we filtered this component and tuned it directly to the extracted 405 kyr eccentricity component of the La2010d orbital solution (Laskar et al., 2011) with maximum a* values, interpreted to represent maximum carbonate dissolution, corresponding to maximum eccentricity values (Table 1). A similar approach was carried out for the a* record of Site 1263 to evaluate the continuity of the successions and robustness of the filtered output (Fig. 2). Finally, the tuned age model of Site 1262 was transferred to Site 1263 by correlating > 50 characteristic features in the a* records of both sites as tie points (Fig. 2 and Table 2).

### Table 1. Age-depth tie points based on the tuning of the filtered 3 m period extracted from the color reflectance record of Site 1262 and the long-eccentricity cycle extracted from the astronomical solution La2010d (Laskar et al., 2011).

Different tuning options have been debated in the last 10 years, resulting in an age for the PETM ranging between ~55.5 and ~56.3 Ma (Lourens et al., 2005; Westerhold et al., 2008; Hilgen et al., 2010; Dinarès-Turell et al., 2014). Here we report on two tuning options (Fig. 2), assigning an age of 53.69 ± 0.02 Ma (option 1) or of 54.09 ± 0.02 Ma (option 2) to ETM2 (Westerhold et al., 2007). According to both options, ETM2 predates the 405 kyr maximum falling at an increasing limb, in agreement with observations of Westerhold et al. (2007), but in contrast with the earlier interpretation by Lourens et al. (2005), who aligned this event to a maximum in the 405 kyr cycle. Recent literature revising the Paleocene cyclostratigraphic interpretation (Dinarès-Turell et al., 2014; Hilgen et al., 2015) has shown that the Paleocene holds 25, rather than 24, 405 kyr eccentricity cycles. In addition, new U/Pb ages have become available which support an age of ~66.0 Ma for the K/Pg boundary (Kuiper et al., 2008; Renne et al., 2013). These developments point to an age of ~54.0 Ma for ETM2 and therefore we plot our results anchoring the age of ETM2 to option 2 (Fig. 4). Evolutionary wavelet spectra were obtained in the time domain using the wavelet script of Torrence and Compo (http://paos.colorado.edu/research/wavelets). Prior to the analysis,
Figure 2. Floating orbitally tuned age model constructed using the red over green color ratio (a*) record of ODP Sites 1262 (red line) and transferred to Site 1263 by using age-depth tie points between the sites (black dots, see Table 2). Two different tuning options are shown based on the ages proposed for the PETM by Westerhold et al. (2008).

carbon and oxygen records were resampled at 2.5 kyr, detrended and normalized.

4 Results

Our new benthic δ13C and δ18O records show six major negative excursions between 54 and 52 Ma (Fig. 4). They correspond to the ETM2, H2, I1, I2, J, and ETM3 (or X/K) events, formerly recognized in deep-sea δ13C bulk carbonate records and land-based marine and continental sections (Abels et al., 2012, 2015; Agnini et al., 2009; Cramer et al., 2003; Kirtland Turner et al., 2014; Littler et al., 2014; Lourens et al., 2005; Slotnick et al., 2012).

The general long-term trend in our ~2 Myr long records indicates a minor increase between 54.2 Ma and 53.2 Ma followed by an average decrease of ~0.3‰ in absolute baseline values of both δ13C and δ18O following J (~53.1 Ma), accompanied by minor cycles between the six main events in both records. Following J, both records maintain rather stable values up to ETM3 (Fig. 4). These changes are negligible compared to the Paleocene-Eocene long-term warming trend and long-term negative trend in carbon isotope values. However, the onset of more generally negative δ13C values, coinciding with J, has also been observed in the deep-sea bulk carbonate record at Site 1262 (Zachos et al., 2010) and in the land-based section at Mead Stream by Slotnick et al. (2012), who suggested that the pronounced change in lithology beginning with J could be used as a chronostratigraphic marker for the onset of the EECO.

Evidence for the onset of warmer temperatures leading to the EECO is evident at ~53 Ma in the benthic δ18O records at both Sites 1262 and 1263 (Fig. 4). Baseline average δ18O values prior to ETM2, signifying the response of the unperturbed oceanic system, indicate a mean deep-sea temperature of ~12°C, which post-J increases by >0.5°C. Despite variability, our data show that this increase in background temperature continued upwards across ETM3. Here we suggest that the onset of the EECO can be identified in our records with the onset of the general low in benthic isotope values initiated with J (~53 Ma) and thus including ETM3 within the EECO. Although longer high-resolution benthic δ18O records are needed to establish the total duration of the EECO, this could represent a first step towards a formal defi-
nition of the warmest interval of the Cenozoic, avoiding ambiguity caused by changes in the timescale.

On the short-term scale, our new data across the events following ETM2 and H2 indicate a rise in temperature of ∼2 °C and ∼1.5 °C during I1 and I2, respectively. The J event was associated with a temperature increase of >1 °C superimposed on the further average decrease in baseline δ¹⁸O value. ETM3 is expressed in both the shallowest and deepest site at Walvis Ridge by similar isotopic excursions, with a CIE of ∼0.8 ‰ and a negative shift in the δ¹⁸O record of ∼0.5 ‰, corresponding to a warming in the deep ocean of 2–2.5 °C, comparable to values observed during the ETM2 (Stap et al., 2010).

Evolutionary wavelet analyses for δ¹³C and δ¹⁸O records of Site 1263 show spectral power concentrated at distinct frequencies, corresponding to the long 405 kyr and short ∼100 kyr eccentricity cycles (Fig. 5). The isotope records reveal coherent patterns, with the highest spectral power corresponding to the deep ocean warming during ETM2 (Stap et al., 2010).
centrated during ETM2-H2 and I1-I2. The ∼100 kyr signal in δ¹³C, which is very prominent in the first 1 Myr of the record, weakens after J. The imprint of precession and/or obliquity forcing is very weak/absent throughout the entire record. As a result of our tuning approach, minima in δ¹³C are approximately in phase with maxima in the 405 kyr and ∼100 kyr eccentricity cycles, following previous work (e.g., Cramer et al., 2003; Lourens et al., 2005; Zachos et al., 2010; Stap et al., 2010).

5 Discussion

5.1 Isotope covariance

Our high-resolution benthic isotope records provide a direct constraint on the relationship between the temperature-related signal carried by the benthic foraminiferal δ¹⁸O and the CIEs during the events leading to the EECO. The six events recognized in the benthic records vary in terms of both magnitude of the CIEs and inferred temperature changes. The most intense perturbations are associated with ETM2, I1 and ETM3, whereas H2 and I2, which lag the larger events by one 100 kyr eccentricity cycle, are less prominent (Fig. 4). One important question then is whether all these events of varying magnitude are accompanied by the same source of light carbon released into the ocean atmosphere system and climatic response. Following Stap et al. (2010), we have assessed this by comparing the slopes of the regression lines between the carbon and oxygen isotopes of the individual events (Fig. 6). These cross-plots clearly show that all events exhibit significant and coherent linear correlation at both sites with slopes ranging between 0.5 and 0.7 (Fig. 6), indicating a consistent relationship for all events between changes in deep-sea temperatures and carbon release. We conclude that this significant covariance between benthic δ¹³C and δ¹⁸O records suggests a strong non-linear response to orbital forcing of global temperatures and the release of isotopically light carbon (e.g. methane gas and/or CO₂) into the ocean-atmosphere system during eccentricity maxima, driving subsequent carbonate dissolution and enhanced greenhouse warming, as has been observed in the older part of the record at Site 1262 (Stap et al., 2010; Littler et al., 2014). This conclusion is further underlined by the consistent scaling of CIE magnitudes between our deep-sea data and soil nodule records of the Bighorn basin for these events, which strengthens the hypothesis of a similar isotopic

Figure 4. Benthic N. truempyi $\delta^{13}C$ and $\delta^{18}O$ records from Site 1263 and Site 1262, plotted versus Age (Ma), (starting from option 2 for the age of ETM2 by Westerhold et al., 2008). Highlighted intervals represent the position of the early Eocene hyperthermal events.

composition of the carbon source for the early Eocene hyperthermal events (Abels et al., 2015).

5.2 The “paired” hyperthermal events

The slopes of the regression lines for H2 and I2 appear slightly steeper than those of ETM2, I1, J and ETM3 (Fig. 6). To statistically test this (dis)similarity, we applied a Student t-test to pairs of slopes, comparing all the events against each other using both a pooled and an unpooled error variance. The results show that the null hypothesis (the slopes being similar, $\alpha = 0.05$) is satisfied in the case of ETM2, I1, J and ETM3. The tests on the steeper slopes of H2 and I2 generally display values of $p \leq 0.05$ when tested against the other events, but values of $p \geq 0.05$ when tested against each other. This implies that the smaller events, H2 and I2, are statistically similar to each other but differ slightly from the other perturbations. Even though this statistical approach might be subject to limitations derived from the range of data points chosen for each event, it clearly shows that the slopes for H2 and I2 deviate from the average values given by the other events. Moreover, the statistical deviation of the slopes of H2 and I2 is clearer when comparing them with the average slope calculated for all the events at each site, since the slopes of H2 and I2 fall outside the (99.99 %) confidence limits (Fig. 7). The average slope between $\delta^{13}C$ and $\delta^{18}O$ of 0.6 for both sites is also in accord with previous observations for the onset/recovery of PETM, ETM2 and H2 by Stap et al. (2010).

The “paired” hyperthermal events, ETM2-H2 and I1-I2 thus reveal slightly different $\delta^{13}C$ vs. $\delta^{18}O$ relationships between their first (ETM2 and I1) and secondary (H2 and I2) pulses. Assuming that these signals are globally representative, this could imply that the second of the two pulses had a relatively larger contribution of an isotopically heavier carbon source than the first pulse. Such a mechanism could hint to a methane-related dominant carbon source (e.g. methane hydrates) during the initial phase of the paired hyperthermal events that is mostly depleted, so that other relatively heavier carbon isotope sources (e.g. wetlands, peat) become progressively more important during the successive event. Warming of intermediate water during ETM2 and I1, as previously suggested for the PETM and ETM2 (Jennions et al., 2015; Lunt et al., 2010), could have destabilized methane clathrates leading to their dissociation and the subsequent increased warming and large CIE. Mechanisms re-
Figure 5. Evolutionary wavelet analyses for δ¹³C and δ¹⁸O were performed using a Morlet mother wavelet of an order of 6. Shaded areas represent 95% significance levels. Spectral power above the confidence level is concentrated at distinct frequencies, corresponding to the long (405 kyr) and short eccentricity (100 kyr) cycles. Highlighted intervals represent the position of the early Eocene hyperthermal events.

Figure 6. Relationship between the oxygen and carbon isotope values of *N. truempyi* during ETM2, H2, I1, I2, J and ETM3/X at Site 1263 and Site 1262. Note that, because of intense dissolution at Site 1263, ETM2 data were chosen from Site 1265 (Stap et al., 2010). For all the events, throughout the entire event (onset + recovery phases), changes in the exogenic carbon pool are linearly related to warming. Linear regression equations refer to Site 1263 (top) and Site 1262 (bottom), respectively.
lated to the depletion and subsequent recharge time of the inferred methane clathrate reservoir between ETM2 and H2, and I1 and I2, could explain why the second event had both a smaller magnitude and possibly a smaller relative contribution of methanogenic carbon. The smaller magnitude of the two secondary carbon pulses, regardless of the isotopic composition of their source, seems feasible because the a* values, interpreted as representative of the degree of carbonate dissolution, were significantly lower than during their preceding counterparts (Fig. 2). In other words, the degree of carbonate dissolution associated with the shoaling of the calcite compensation depth (CCD) and lysocline appears to be less severe than during the first pulses. In this respect it is worth noting that H2 and I2 also behave differently from the “larger” events in terms of biotic disruption. During PETM, ETM2 and I1, rates of variability in planktonic communities indicate that the biotic response was proportional to the magnitude of carbon injections, and biotic disruption linearly declined along with the decreasing size of CIEs (Gibbs et al., 2012; Jennions et al., 2015). However, H2 and I2 do not show evidence of above-background variance, suggesting that during these events the system apparently failed to cross the environmental “threshold” necessary to generate a detectable marine biotic disruption (D’haenens et al., 2012; Gibbs et al., 2012). This all suggests that a change in the climate feedbacks and/or an incomplete recovery of the buffering capacity of the ocean system after the first perturbation could have played a significant role in amplifying the temperature response during the secondary pulse. On the other hand, we cannot dismiss the possibility that local circulation changes and/or partial dissolution slightly altered the anomalies in δ18O and δ13C during H2 and I2 at Walvis Ridge. Further research is hence needed to ratify the (global) significance of this finding.

5.3 Thresholds and orbital pacing

The transition towards the EECO is marked by a general decrease of both benthic carbon and oxygen isotopic values of ~0.3‰ at Site 1263, indicative of both long-term warming and progressive oxidation of organic matter releasing CO2 into the ocean-atmosphere system. It has been theorized that the timing and magnitude of the hyperthermals would respond to the crossing of a thermal threshold, more frequently reached in phases of orbital-driven temperature increase (Lourens et al., 2005; Lunt et al., 2011). In addition, the carbon reservoir or capacitor (Dickens, 2003), regardless of its nature and as a result of the long-term temperature increase from the late Paleocene to the early Eocene, would be largely depleted by the peak of the EECO, leading to an interval free of hyperthermals. In turn, a series of orbitally paced global warming events of decreasing frequency and increased size are expected to occur during the post-EECO cooling phase when the carbon reservoir would have been progressively refilled (e.g., Kirtland Turner et al., 2014). This hypothesis has been questioned with data from a composite bulk stable isotope record of Site 1258 showing that a series of negative stable isotope excursions continued throughout the EECO. This evidence suggests that episodes of carbon release persisted during the peak of warmth and the onset of the cooling trend (Kirtland Turner et al., 2014). Kirtland Turner et al. (2014) suggest that the mechanisms operating in the early Eocene climate were not necessarily exceptional but actually similar to those invoked for the Oligocene and Miocene when cyclic variations in the carbon cycle were also clearly paced by orbital forcing, particularly in the eccentricity bands (Holbourn et al., 2007; Pälike et al., 2006; Zachos et al., 2001b). Although the carbon and oxygen isotope records of the Oligocene-Miocene and early
Eocene are certainly paced by eccentricity, their appearance in terms of punctuation are clearly different. In particular, a relatively sudden release (storage) of large amounts of light carbon (e.g. methane hydrates) into the ocean-atmosphere system seems the only way to explain the unusual magnitude of the CIEs recorded at Walvis Ridge given the rate and/or magnitude of warming, as well as carbonate dissolution and changes in benthic assemblages associated with those events (Jennions et al., 2015; Stap et al., 2009).

5.4 Site 1263 vs. Site 1262

Comparison between the benthic $\delta^{13}$C and $\delta^{18}$O records of Sites 1263 and 1262 reveals an almost identical pattern, although $\delta^{18}$O values of Site 1263 are consistently $\sim 0.2\%$ heavier than those of Site 1262 (Figs. 3 and 4). A similar (reversed) pattern has been previously observed by Stap et al. (2009) in the case of ETM2, and attributed to differential dissolution from the shallowest to the deepest site. Conversely, selective dissolution seems unlikely to justify the persistent offset in $\delta^{18}$O values observed throughout the new post-ETM2 record presented herein. We posit that this offset may be linked to a different average isotopic composition of the water masses at those sites. Accordingly, the intermediate water masses reaching Site 1263 were more $^{18}$O-enriched than the deeper waters at Site 1262. The existence of a discrete intermediate water body in the early Eocene South Atlantic is supported by recent benthic foraminiferal assemblage, sedimentological evidence and Earth system modeling data across ETM2, which suggests that warming in the intermediate waters bathing Site 1263 led to differential patterns in sedimentary and ecological data between this site and the deeper Site 1262 (Jennions et al., 2015).

6 Conclusions

New high-resolution benthic stable isotope records from ODP Sites 1262 and 1263 provide a detailed framework to explore the (transient) nature of early Eocene hyperthermal events during the onset of the Eocene. Our results further confirm the link between large-scale carbon release and climate response to orbital forcing, in particular to short- and long-eccentricity cycles. The transition towards the EECO is marked by a general decrease of both benthic carbon and oxygen isotopic values of $\sim 0.3\%$ at Site 1263, indicative of both long-term warming and progressive oxidation of organic matter releasing CO$_2$ into the ocean-atmosphere system. Consistent covariance between benthic carbon and oxygen isotopes demonstrates that global temperatures and changes in the exogenic carbon pool were similarly coupled during each of the studied hyperthermal events. In this regard, we found that the second pulses of the paired hyperthermal events (i.e. H2 and I2) point to a slightly different behavior. Whether this implies a larger role for a carbon reservoir characterized by a heavier isotopic signature remains debatable and, hence, allows for further consideration of other operational processes such as local circulation changes, partial dissolution, or different climate feedbacks. Finally we found a constant offset in oxygen isotopic values between Site 1263 and 1262, with the isotopic composition of the shallower waters at Site 1263 consistently heavier than at Site 1262, suggesting the presence of a discrete water body at intermediate depths of the Walvis Ridge transect.

Acknowledgements. We are grateful to Gerald Dickens, Lee Kump and Philip Sexton for their constructive comments. We thank the International Ocean Discovery Program (IODP) for providing the samples used in this study. We also thank A. van Dijk at Utrecht University, and Dyke Andreasen and Chih-Ting Hsieh at UCSC for analytical support. This research was funded by NWO-ALW grant (project no. 865.10.001) to L. J. Lourens. We thank F. Hilgen and H. A. Abels for providing valuable comments on the manuscript.
