Abstract. Transient greenhouse warming events in the Paleocene and Eocene were associated with the addition of isotopically light carbon to the exogenic atmosphere–ocean carbon system, leading to substantial environmental and biotic change. The magnitude of an accompanying carbon isotope excursion (CIE) can be used to constrain both the sources and amounts of carbon released during an event and also to correlate marine and terrestrial records with high precision. The Paleocene–Eocene Thermal Maximum (PETM) is well documented, but CIE records for the subsequent warming events are still rare, especially from the terrestrial realm.

Here, we provide new paleosol carbonate CIE records for two of the smaller hyperthermal events, I1 and I2, as well as two additional records of Eocene Thermal Maximum 2 (ETM2) and H2 in the Bighorn Basin, Wyoming, USA. Stratigraphic comparison of this expanded, high-resolution terrestrial carbon isotope history to the deep-sea benthic foraminiferal isotope records from Ocean Drilling Program (ODP) sites 1262 and 1263, Walvis Ridge, in the southern Atlantic Ocean corroborates the idea that the Bighorn Basin fluvial sediments record global atmospheric change. The ∼34 m thicknesses of the eccentricity-driven hyperthermals in these archives corroborate precession forcing of the ∼7 m thick fluvial overbank–avulsion sedimentary cycles. Using bulk-oxide mean-annual-precipitation reconstructions, we find soil moisture contents during the four younger hyperthermals that are similar to or only slightly wetter than the background, in contrast with soil drying observed during the PETM using the same proxy, sediments, and plant fossils.

The magnitude of the CIEs in soil carbonate for the four smaller, post-PETM events scale nearly linearly with the equivalent event magnitudes documented in marine records. In contrast, the magnitude of the PETM terrestrial CIE is at least 5 ‰ smaller than expected based on extrapolation of the scaling relationship established from the smaller events. We evaluate the potential for recently documented, nonlinear effects of pCO2 on plant photosynthetic C-isotope fractionation to explain this scaling discrepancy. We find that the PETM anomaly can be explained only if background pCO2 was at least 50 % lower during most of the post-PETM events than prior to the PETM. Although not inconsistent with other pCO2 proxy data for the time interval, this would require declining pCO2 across an interval of global warming. A more likely explanation of the PETM CIE anomaly in pedogenic
carbonate is that other environmental or biogeochemical factors influencing the terrestrial CIE magnitudes were not similar in nature or proportional to event size across all of the hyperthermals. We suggest that contrasting regional hydro-climatic change between the PETM and subsequent events, in line with our soil proxy records, may have modulated the expression of the global CIEs in the Bighorn Basin soil carbonate records.

1 Introduction

During the late Paleocene and early Eocene around 60 to 50 million years ago, massive amounts of carbon were released in pulses into the ocean–atmosphere exogenic carbon pool causing a series of transient global warming events, known as hyperthermals (Kennett and Stott, 1991; Cramer et al., 2003; Zachos et al., 2005; Lourens et al., 2005). These events represent the best paleoanalogs for current greenhouse gas warming, despite the very different background climatic, atmospheric, and geographic conditions, and potentially the different timescales on which they occurred (Bowen et al., 2006, 2015; Zachos et al., 2008; Cui et al., 2011). The largest of the hyperthermals, the Paleocene–Eocene Thermal Maximum (PETM) at 56 million years ago, is known to have caused severe climatic and marine and terrestrial biotic change (Thomas, 1989; Gingerich, 1989; Kennett and Stott, 1991; Koch et al., 1992), comprehensively reviewed in McInerney and Wing (2011). Recently, records of the secondary hyperthermals (i.e., Eocene Thermal Maximum 2 (ETM2–H1) and 3 (ETM3–K)) have become available (Cramer et al., 2003; Lourens et al., 2005; Nicolo et al., 2007; Abels et al., 2012; Chen et al., 2014; Lauretano et al., 2015), while their environmental and biotic impact has yet to be resolved (Sluijs et al., 2009; Stap et al., 2010a, b; Abels et al., 2012; D’Haenens et al., 2014).

All hyperthermals are characterized by a distinct geochemical signature, a negative carbon isotope excursion, indicating that the carbon released to the exogenic carbon pool during these events had a dominant biogenic origin (Dickens et al., 1995). The potential biogenic sources range from plant material to methane. With the carbon isotope excursions and independent constraints on the mass of carbon release, it should be possible to identify the source. The mass can be constrained by several approaches, for example quantifying ocean acidification or pCO2 by proxy, either directly (e.g., by epsilon ϵ) or indirectly (e.g., by sea surface temperature, SST) (Dickens et al., 1997; Dickens, 2000; Bowen et al., 2004; Ridgwell, 2007; Panchuk et al., 2008; Zeebe et al., 2009), though the uncertainty with these approaches is large (Sexton et al., 2011; DeConto et al., 2012; Dickens, 2011). Nevertheless, in theory, if there was a single source of carbon for all carbon isotope excursion (CIE), the scaling with mass should be predictable. This requires that, firstly, the exact size of the CIEs in the global exogenic carbon pool during hyperthermal events be well constrained and, secondly, the factors that fractionating C isotopes between the substrate reservoirs and organic and carbonate proxies be well understood (Sluijs and Dickens, 2012).

Paleosol or pedogenic carbonate is precipitated from CO2 that stems from respiration of roots and plant litter in the soil and from atmospheric CO2 diffusing into the soil. Plant CO2 from C3 plants is typically fractionated by −16 to −24‰ compared to atmospheric CO2 (O’Leary, 1988). Paleosol carbonate is a mix of both isotopically distinct sources, modified by fractionation associated with diffusion, carbonate equilibrium, and calcite precipitation and therefore registers values between −7 and −11‰ in non-hyperthermal conditions in Paleogene soils covered by C3 vegetation. Paleosol carbonate records the atmospheric carbon isotope excursions related to the PETM, though amplified with respect to marine carbonate (Bowen et al., 2004). This amplification has been attributed to increased soil productivity and humidity during the hyperthermal events (Bowen et al., 2004; Bowen and Bowen, 2008) by changing plant communities (Smith et al., 2007) and by higher ρCO2 (Schubert and Jahren, 2013).

In a recent study, the carbon isotope anomalies associated with ETM2 and H2 were documented in paleosol carbonate, allowing for comparison of the terrestrial amplification of the CIEs relative to the PETM (Abels et al., 2012). An apparent linear scaling of the marine and terrestrial carbon isotope excursions for the PETM. ETM2 and H2 events was invoked to suggest that all three events may have reflected a common mechanism of global change. Interpretation of this signal is complicated, however, by shifting background climate conditions between the events, which are separated by close to 2 million years of gradual greenhouse warming (Zachos et al., 2008; Littler et al., 2014), and by the fact that the observed relationship did not converge on the origin, leaving the carbon isotope scaling associated with smaller events (e.g., I1 and I2) uncertain.

Here, we extend the existing record of three hyperthermals from the Bighorn Basin with data documenting two new CIEs (I1 and I2). We further report additional records of the ETM2 and H2 CIEs within the Basin and analyze bulk oxides in thick (> 0.75 m) soils to reconstruct soil moisture values through these greenhouse warming events. We compare our records with the new benthic foraminiferal records generated for Ocean Drilling Program (ODP) Site 1263 at Walvis Ridge, Atlantic Ocean (Lauretano et al., 2015), and a bulk sediment carbon isotope record from ODP Site 1262 (Zachos et al., 2010; Littler et al., 2014), Walvis Ridge, to investigate coeval carbon isotope change and registration of multiple CIEs in the different carbonate proxies. We analyze these records in the context of the recently characterized dependence of plant carbon isotope fractionation on atmospheric CO2 partial pressure (Schubert and Jahren, 2012), including scenarios that allow for changing background conditions across the late-Paleocene–early-Eocene.

Analytical precision is ±0.1 ‰ for δ13C (1σ), possibly noise related to local environmental factors. The spacing between the CIEs and the low-amplitude variability in the MCP section is on average ∼ 34 m. Bandpass filtering of this scale of variability specifically shows a strong coherent variation through the ETM2 to I2 interval (Fig. 3).

Precession forcing of overbank–avulsion lithological cyclicity in the Willwood Formation was recently substantiated with data from the Deer Creek Amphitheater section (Abels et al., 2013). In the DCA section, the cyclicity occurs on a scale of ∼ 7.1 m. In the three sections now covering ETM2–H2, the cyclicity has a very similar average thickness calculated as the difference between pre-excursion carbon isotope values and excursion values within the core of the main body (Table 1; Supplement). Standard errors are calculated using variability in background and excursion values.

3 Results

3.1 Bighorn Basin

High-resolution pedogenic carbonate carbon isotope records are constructed for the lower Eocene of the Willwood Formation in the McCullough Peaks area, northern Bighorn Basin, Wyoming (USA; Fig. 1). Previous work included the Upper Deer Creek (UDC) section, where the carbon isotope excursions of ETM2 and H2 hyperthermal events were located (Abels et al., 2012). Here, we analyze two parallel sections, the Creek Star Hill (CSH) and West Branch (WB) sections, separated by 1 to 2 km from the UDC section (Fig. 1). The isotope record is extended upwards in the WB section and downwards in the Deer Creek Amphitheater section (DCA; Abels et al., 2013). We construct a composite stratigraphic section by connecting the four sections via lateral tracing of marker beds in the field, such as the P1 to P8 purple soils in the ETM2–H2 stratigraphic interval (Abels et al., 2012).

The carbon isotope record of paleosol carbonate of the McCullough Peaks (MCP) composite section shows four CIEs (Fig. 2). The lower excursions of ∼ 3.8 and ∼ 2.8 ‰ in magnitude (see methods for CIE magnitude calculation) have previously been related to the ETM2–H1 and H2 events (Abels et al., 2012) and are shown to be similar in the parallel Upper Deer Creek, West Branch, and Creek Star Hill sections. This confirms the presence and regional preservation of these CIEs in the Willwood Formation. The two younger carbon isotope excursions are ∼ 2.4 and ∼ 1.6 ‰ in magnitude and both located in the West Branch section (Fig. 2). These excursions likely relate to the CIEs of the I1 and I2 events that occur in the subsequent 405 kyr eccentricity maximum after ETM2–H1 and H2 (Cramer et al., 2003).

Besides these CIEs, several intervals show less well-defined negative carbon isotope excursions of ∼ 0.5–1 ‰: two below ETM2 at MCP meter levels 95 and 145, two above H2 at meter levels ∼ 260 and ∼ 290, and one above I2 at meter 400. This scale of variability is harder to detect as the carbon isotopes show a background variability of ∼ 1 ‰ (2σ), possibly noise related to local environmental factors. The spacing between the CIEs and the low-amplitude variability in the MCP section is on average ∼ 34 m. Bandpass filtering of this scale of variability specifically shows a strong coherent variation through the ETM2 to I2 interval (Fig. 3).

Precession forcing of overbank–avulsion lithological cyclicity in the Willwood Formation was recently substantiated with data from the Deer Creek Amphitheater section (Abels et al., 2013). In the DCA section, the cyclicity occurs on a scale of ∼ 7.1 m. In the three sections now covering ETM2–H2, the cyclicity has a very similar average thickness...
Table 1. Magnitudes of carbon isotope excursions for five Paleocene–Eocene hyperthermal events in paleosol carbonate of the Bighorn Basin, Wyoming (USA), and benthic foraminiferal and bulk sediment carbonate of Walvis Ridge sites 1263 and 1262, Atlantic Ocean. Standard errors (SEs) of the differences between detrended background variability and excursion variability are given (see the “Material and methods” section).

Figure 2. Carbon isotope stratigraphies of paleosol carbonate in the McCullough Peaks area, Bighorn Basin, Wyoming (USA). Shown are data from the Upper Deer Creek section of Abels et al. (2012), and the West Branch, Deer Creek Amphitheater, and Creek Star Hill sections. Grey horizontal lines represent field-based tracing of marker beds P1, P4, and P8 by which the McCullough Peaks composite carbon isotope stratigraphy has been constructed. To the right, mean annual precipitation reconstructions from the CAL-MAG methods are given on the McCullough Peaks composite stratigraphy. Different symbols denote different thickness of the soil-B horizons. Note that there is no obvious change in soil moisture during the four hyperthermal events.

Figure 3. The McCullough Peaks paleosol carbonate carbon isotope stratigraphy compared in-depth domain to the bulk sediment and benthic foraminiferal (Nuttallides truempyi) carbon isotope stratigraphies at, respectively, ODP Site 1262 (left y axis on right side; Zachos et al., 2010) and 1263 (right y axis on right side; Stap et al., 2010a; this study) at Walvis Ridge in the southern Atlantic Ocean. Filters denote the ∼100 kyr eccentricity band in the three records. Note that linear stretching of depth scales is sufficient to construct the figure, indicating the constant average sedimentation rates on longer timescales in both realms. On smaller timescales, large sedimentation rate differences occur that in the marine realm relate to carbonate dissolution during and carbonate overshoot after the hyperthermal events.
precession forcing sedimentary synthesis, the heterolithic inter-
ervals are related to periods of regional avulsions and rapid
sedimentation, while the mudrocks are related to periods of
overbank sedimentation when the channel belt had a rela-
tively stable position (Abels et al., 2013). This scale of sedi-
mentary cyclicity is also observed higher in the West Branch
section. Average climatic precession cycles in the Eocene
last ~20 kyr resulting in ~7.1 m of sediment. This gives an
average sedimentation rate of ~0.35 m kyr⁻¹, resulting in
~96 kyr for the 34 m cyclically observed in the carbon iso-
tope records in the ETM2–I2 interval. This is in line with
~100 kyr eccentricity forcing of individual hyperthermals and
a 405 kyr eccentricity forcing of the ETM2–H2 and I1–I2
couples.

We produce MAP estimates across the ETM2–I2 interval
with the CALMAG method, which uses bulk oxide ratios in
soil-B horizons (Nordt and Driese, 2010). Conservatively
the method reconstructs soil moisture contents in these an-
cient soils. Ideally, soil-B horizons thicker than 1 m should
be used for this proxy (Adams et al., 2011). We measured all
59 soil-B horizons thicker than 1 m, where possible in multi-
ple, parallel sections. In addition, we measure 24 soil-B hori-
zons between 0.5 and 1 m. Our estimates from the 83 indi-
vidual soils show a stable soil moisture regime in the early
Eocene Bighorn Basin with mean annual precipitation esti-
mates of around 1278 mm yr⁻¹ (2σ 132 mm yr⁻¹; Fig. 2).
All except one soil-B horizon thicker than 1.25 m fall in this
range. Soil-B horizons below 1.25 m thickness occasionally
show drier outliers, of which three are below 1000 mm yr⁻¹.
There are no striking changes during the ETM2, H2, I1,
or I2 hyperthermal events. The 5 soils that contribute to
our ETM2 reconstructions show a potentially slightly en-
hanced soil moisture content with reproduced annual rain-
fall of 1337 (2σ 88 mm yr⁻¹), while the 11 soils in H2 show
1267 mm yr⁻¹ (±166), no different from reconstructions for
background climate states. There are slightly more dry out-
liers both in as well as just outside the hyperthermals, espe-
cially H2, but it should be noted that these intervals also have
denser sampling because of the replication of data for these
intervals in three parallel sections.

3.2 Walvis Ridge

For a comparison of time equivalent carbon isotope change,
we use existing and new benthic foraminiferal Nuttallides
truempyi records from Site 1263 (McCarren et al., 2008; Stap
et al., 2010a; Lauretano et al., 2015), the shallowest site of
Walvis Ridge, with a paleodepth of ~1500 m. For Site 1263,
because N. truempyi specimens are absent in the main body of
the PETM, the benthic record includes data for the in-
faunal species Oridorsalis umbonatus, which is isotopically
similar (McCarren et al., 2008). The O. umbonatus data cover
most of the CIE though no shells were recovered from the
lowermost portion of the clay layer. Data for the ETM2–H2
events are from Stap et al. (2010a), and data for I1–I2 are
from Lauretano et al. (2015). Benthic foraminifera are mostly
absent within the Elmo clay layer at Site 1263. A compila-
tion of all Walvis Ridge sites shows very similar benthic car-
bon isotope excursion values for ETM2 (Stap et al., 2010a).
Therefore, we use the next-shallowest site, 1265 (paleodepth
~1850 m), to cover the missing ETM2 peak excursion val-
ues at Site 1263. The data from N. truempyi at Site 1263,
generated at 5 cm resolution across the I1 and I2 events, show
benthic CIEs of 0.88 ‰ for I1 and 0.73 ‰ for I2 (Fig. 3).

As a framework for correlation, we plot the long, high-
resolution bulk carbonate carbon isotope record from ODP
Site 1262 (Zachos et al., 2010) and the benthic carbon isotope
record from ODP Site 1263 (Fig. 3). Site 1262 is the deep-
est site from the ODP Leg 208 Walvis Ridge transect, with
an approximate paleodepth of 3600 m. The Site 1262 carbon
isotope record is orbitally tuned (Westerhold et al., 2008) and
captures all Eocene CIE, PETM, ETM2, H2, I1 and I2 events
(Zachos et al., 2010; see also Littler et al., 2014), though the
PETM is clearly truncated due to dissolution (Zachos et al.,
2005).

3.3 CIE comparison with fixed background $pCO_2$

The new records show that CIE magnitudes of both ter-
restrial and marine substrates decrease progressively across
the five hyperthermal events (Fig. 4). For the four smaller
events, the pedogenic carbonate and benthic foraminifera
records are strongly linearly correlated ($r^2 = 0.97$). The data
for the larger PETM event, however, deviate strongly from
this trend. As described above, it has previously been ob-
erved that Eocene hyperthermal pedogenic carbonate CIEs
are generally amplified in magnitude relative to their marine
counterparts (Bowen et al., 2004; Smith et al., 2007; Schu-
bert and Jahren, 2013). The new data suggest that the mech-
anisms leading to this amplification were stronger, relative
to the size of the event, for the smaller events than for the
PETM.

We evaluate this observation in the context of one mech-
anism, i.e., the sensitivity of land plant photosynthetic $^{13}$C
discrimination to change in $pCO_2$, which may affect the C-
isotope offset between marine and terrestrial substrates dif-
f ferently among events. We conduct two sets of model ex-
periments, adopting a common framework for both based on
the assumption that the carbon sources and nature of envi-
ronmental change during each event were comparable. Al-
though this assumption is likely oversimplistic, it allows us
to evaluate the effects of the photosynthetic discrimination
mechanism in isolation and to directly evaluate its potential
contribution to CIE expression in the new terrestrial records.
Specifically, we assume that for each event the CIE magni-
tude in the atmosphere ($D_{a,b}$) is equal to the CIE magni-
tude in marine (benthic) CIE magnitude, which is to some
extent supported by the temperature change derived from

www.clim-past.net/12/1151/2016/
D$^{18}$O scaling with D$^{13}$C (Stap et al., 2010a; Lauretano et al., 2015), such that

$$D_{ph} = D_{PETM}^p \times D_{s.h} / D_{s.PETM}^p.$$  

As a starting point for our analysis, we use C-isotope data from leaf wax lipids that constrain the magnitude of the PETM CIE within Bighorn Basin plants ($D_{ph,PETM}^p \approx -4.2\%e$; Smith et al., 2007). Decomposing the plant CIE into

$$D_{p,PETM} = D_{s,PETM}^p - D_{PETM}^p,$$

where $\Delta$ is photosynthetic C-isotope discrimination, we solve for the change in discrimination during the PETM (+$0.8\%e$ using the Walvis Ridge benthic data to estimate $D_{s,PETM}^p$).

For any background $p$CO$_2$ condition prior to the PETM ($p_{bkg,PETM}$), we can calculate an estimate of plant carbon isotope discrimination ($D_{bkg,PETM}$) using Eq. (6) of Schubert and Jahren (2012). This idealized value corresponds to fractionation for plants under experimental conditions that are not water or light limiting and is used throughout our modeling when we refer to values of $\Delta$. Adding this value to $D_{PETM}^p$, we obtain an equivalent value for PETM photosynthetic discrimination, $\Delta_{PETM}$. We then invert the photosynthetic discrimination equation to find the PETM $p$CO$_2$ concentration ($p_{PETM}$) that gives the estimated discrimination:

$$p_{PETM} = (\Delta_{PETM} \times a/b + \Delta_{PETM} \times c - a \times c)/(a - \Delta_{PETM}).$$  

where $a = 28.26$, $b = 0.21$, and $c = 25$ are empirically optimized parameter values (Schubert and Jahren, 2012). Although environmental and physiological factors almost certainly caused the actual, absolute magnitude of plant carbon isotope discrimination in the Paleocene–Eocene Bighorn Basin to be different from the $\Delta$ values calculated here, our results depend only on the change in $\Delta$ between background and hyperthermal conditions and thus on the assumption that the form of the discrimination equation accurately describes the response of Bighorn Basin plants. Below, we discuss how changes in other environmental parameters during hyperthermals may compromise this assumption. We used this approach to calculate values of $p_{PETM}$ and change in PETM $p$CO$_2$ ($D_{PETM}^p$) across a range of assumed background $p$CO$_2$ conditions from 250 to 3000 ppmv (figure given in Appendix Fig. B1).

Building on this framework, our first set of model experiments assumes an invariant background $p$CO$_2$ value across all five events to evaluate whether the nonlinear response of changing photosynthetic discrimination to a range of $D_{ph}^p$ magnitudes across the events can explain the nonlinear CIE scaling observed in the terrestrial records. Using $p_{bkg,h} = p_{bkg,PETM}$ and the $D_{ph}$ values estimated for each event, we calculated $D_{\Delta}$ for each event using the previously referenced photosynthetic discrimination equation. We then apply Eq. (2) to each event to calculate an estimate of $D_{\Delta}^p$ and compare the implied plant CIE magnitude ($CIE^p_\beta = 0 - D_{p}^\beta$) with the observed soil carbonate CIEs to evaluate whether these scale proportionally across all five events. If change in plant discrimination explains the nonlinear scaling of the paleo-carbonate CIE magnitudes ($CIE_\beta$), assuming all other soil or environmental influences scale proportionally with event magnitude, then we expect that for all events

$$CIE_\beta = CIE_p, h \times b_1 + b_0.$$  

Nowhere within the range of background $p$CO$_2$ values tested here is this the case (Fig. 5), suggesting that changing photosynthetic discrimination in isolation and under the assumption of near-constant background $p$CO$_2$ cannot explain the variation in CIE expression in Bighorn Basin soil carbonates. The exercise shows that large changes in absolute background $p$CO$_2$ values do not significantly impact the results.
Figure 5. Carbon isotope excursions (CIEs) for the PETM, ETM2, H2, I1, and I2 events in the early Eocene compared between paleosol carbonate (y axis) CIEs in the Bighorn Basin, Wyoming (USA), and measured and modeled plant CIE for two extreme initial pCO2 scenarios. The plant CIE for the PETM is measured (Smith et al., 2007); those of the younger four hyperthermals are modeled (see text for explanation). Note that the trend lines for both extreme pCO2 scenarios do not fit the measured CIEs in plant and pedogenic carbonate for the PETM.

3.4 Impact on CIE magnitudes of variable background pCO2

For our second set of experiments, we allow background pCO2 (p_bkg) to change across the study interval and evaluate the p_bkg conditions required to reconcile the observed pattern of soil carbonate CIE magnitudes with the marine record. Our initial assumptions and estimates of PETM discrimination and pCO2 change are as described in Sect. 3.3.

Here we assume that Eq. (4) does describe the relationship between plant and soil carbonate CIEs and that there are no fixed offset effects (i.e., p_b = 0; all factors that affect the size of the carbonate CIEs relative to the plant CIEs scale linearly with event size). It follows that the plant CIE magnitude for each event is

\[ D_{\delta_{p,h}} = D_{\delta_{p,PETM}} \times D_{\delta_{c,h}} / D_{\delta_{c,PETM}}. \]  (5)

We then calculate the change in photosynthetic discrimination for each event as

\[ D_{\Delta_h} = D_{\delta_{a,h}} - D_{\delta_{p,h}}. \]  (6)

We now have two differences, D_p_h and D_{\Delta_h}, for each event. From the photosynthetic discrimination equation, we can write

\[ D_{\Delta_h} = \frac{ab(p_{bkg,h} + D_p + c)}{a + b(p_{bkg,h} + D_p + c)} - \frac{ab(p_{bkg,h} + c)}{a + b(p_{bkg,h} + c)}. \]  (7)

This can be rearranged to give

\[ b^2 p_{bkg,h}^2 + b(2a + 2bc + bD_p) p_{bkg,h} = a^2 + 2abc + abD_p_h + b^2c(D_p_h + c) - \frac{a^2bD_p_h}{D_{\Delta_h}}, \]  (8)

a quadratic equation which can be solved to obtain the background pCO2 value required for each hyperthermal to give linear scaling between CIE_p and CIE_c across the events (at any prescribed value of p_{bkg,PETM}).

The analysis suggests that the nonlinear scaling of the soil carbonate CIEs relative to the marine record can be explained across the entire range of assumed p_{bkg,PETM} conditions through changes in photosynthetic 13C discrimination forced by hyperthermal pCO2 increase over varying background pCO2 conditions (Fig. 6). For any assumed PETM background pCO2, our results require a > 50% decrease in background pCO2 during the ∼2 Myr interval separating the PETM and ETM2. The analysis requires sustained, low background pCO2 which rises gradually across the two subsequent events before a more abrupt increase prior to the I2 event. Across most of the range of initial conditions evaluated, the results require non-hyperthermal background pCO2 values substantially lower than p_{bkg,PETM} throughout the early Eocene. The fractional change in pCO2 required, relative to PETM background conditions, is lower for higher assumed p_{bkg,PETM}, but larger absolute changes in pCO2 are required for these cases.
4 Discussion

4.1 Fluvial sedimentary archives of the Bighorn Basin

The presence of five carbon isotope excursions demonstrates that the river floodplain sedimentary successions in the Bighorn Basin firmly record these global atmospheric events. The two new parallel series in the Bighorn Basin confirm the presence of ETM2 and H2 (Abels et al., 2012). The records of the I1 and I2 events represent the first equivalents in fluvial strata. In the terrestrial realm, a CIE has been found in coal seams in the Fushun Basin, China, which has been related to I1 (Chen et al., 2014), while I2 has not yet been recorded in any other terrestrial record.

The bulk oxide CALMAG proxy data have been proposed to reflect MAP through its influence on soil mineral weathering and cation leaching (Nordt and Driese, 2010; Adams et al., 2011). Here, we conservatively use the method as a proxy for soil moisture rather than mean annual precipitation. The data indicate no or slight increases in soil moisture during the four early Eocene hyperthermals. This strongly deviates from observations of paleohydrologic change for the PETM in the northern and southern Bighorn Basin, where the same proxy indicates a decrease in soil moisture (Kraus and Riggins, 2007; Kraus et al., 2013), consistent with a soil morphology index (Kraus et al., 2013), and analysis of fossil leaves (Wing et al., 2005; Kraus et al., 2013). This would suggest that the regional climatic and/or environmental response to the PETM differed from the post-PETM hyperthermals.

Besides precipitation, temperature, vegetation, and sediment type and rates also have a large impact on soil moisture, and changes in CALMAG geochemical data should be considered in light of changes in these factors (Kraus et al., 2013). For the four younger hyperthermals, there are no temperature or vegetation data available for the Bighorn Basin, while the impact of sediment type and rates needs to be investigated for all five hyperthermals. In this sense, it remains unclear whether the observed opposite CALMAG changes between PETM and the four post-PETM hyperthermals relate to diametrically opposed precipitation trends or environmental (depositional) trends.

The precession forcing of the 7 m thick overbank–avulsion sedimentary cycles (Abels et al., 2013) is in line with ~100 and 405 kyr eccentricity forcing of the carbon cycle changes in the ETM2 to I2 stratigraphic interval (Fig. 3). Mudrock intervals with well-developed purple and purple–red paleosols occur predominantly in the eccentricity maxima, while the minima seem to be richer in sand. This could point to a more prolonged relatively stable position of the channel belt on the floodplain, causing less coarse clastic deposition on the floodplains, during eccentricity maxima (Abels et al., 2013). Such an effect could have occurred in combination with or due to more intense pedogenesis under warmer and wetter climates. However, in this interval, the eccentricity-related change is dominated by the hyperthermal events and corroboration of the eccentricity impact is needed from an interval lacking hyperthermals.

4.2 Marine–terrestrial correlations

The benthic carbon isotope record of the I1 and I2 events at Site 1263 reveal very similar patterns as in the bulk and benthic carbon isotope record of Site 1262 (Zachos et al., 2010; Littler et al., 2014) on both eccentricity and precession timescales, as was indicated previously for ETM2 and H2 (Stap et al., 2009). These records even capture very detailed features such as the short-term pre-ETM2 and pre-H2 excursions, and a similar pattern in the I2 excursion. These patterns were clearly driven by changes in the carbon isotope ratio of the atmosphere–ocean exogenic carbon pool as related to precession forcing (Stap et al., 2009).

Some of these precession-scale details are also captured by the pedogenic carbonate carbon isotope record from the Bighorn Basin suggesting their global nature (Fig. 3). A pre-ETM2 excursion occurs in the McCullough Peaks composite at meter 183, while the shape of the I2 excursion is remarkably similar to the marine records. Main differences on these depth-scale plots are the relative expanded CIE intervals and short recovery phases between H1 and H2 and between I1 and I2 in the Bighorn Basin with respect to the Atlantic Ocean records. Sediment accumulation rates were influenced by carbonate dissolution during the events and carbonate overshoot after the events in the marine realm. At the same time, in the Bighorn Basin, sedimentation rates might have been higher during the events due to increased sediment budgets and subsequently lower during their recovery phases. These processes might cause the expanded CIEs and contracted recovery phases in the Bighorn Basin with respect to the marine records when comparing them on a depth scale.

4.3 Pedogenic carbon isotope excursions

Deciphering the true scale and timing of ocean–atmosphere Δδ13C during hyperthermal events is hampered by environmental impacts on carbon isotope fractionation between marine and terrestrial substrates and their proxies (Slujs and Dickens, 2012). Our comparison of pedogenic carbonate and marine carbon isotope excursions across the five hyperthermal events shows that although each of the CIEs is amplified in magnitude in the soil carbonate records, the PETM soil carbonate CIE magnitude is anomalously small relative to the pattern of amplification seen for the other events. The use of other marine records in this comparison provides similar results. Changes in photosynthetic 13C discrimination alone cannot explain the anomalously small PETM soil carbonate CIE if we assume that background pCO2 conditions were similar across each of the events (Fig. 5). This mechanism can explain the soil carbonate CIE scaling across the events if there are substantial changes in background pCO2, but the
required changes involve a > 50% decline in $\rho CO_2$ from the end of the Paleocene to the early Eocene. This pattern is not inconsistent with independent $\rho CO_2$ proxy data from this time interval, but the existing records are too variable and imprecise to provide clear support for or conclusively refute our result (Jagniecki et al., 2015).

Reconciling the pattern of $\rho CO_2$ change inferred in our analysis with known changes in global climate of the early Eocene is more challenging. The dramatic reduction in $\rho CO_2$ we estimate following the PETM would be expected to align with a decrease in global temperatures. Although transient cooling has been documented during the ~2 Myr following the PETM (Wing et al., 1999), temperatures had recovered to at least pre-PETM levels by the time of the ETM2, and thereafter continued to warm toward the peak Cenozoic values of the Early Eocene Climate Optimum (Zachos et al., 2008). Benthic oxygen isotope data of Walvis Ridge, Atlantic Ocean, show a ~1 °C increase in deep-sea temperature between PETM and ETM2 baseline values (Littler et al., 2014). The substantially lower background $\rho CO_2$ values required by our analysis for ETM2 and the subsequent hyperthermals would thus imply that non-CO$_2$ greenhouse gases or other mechanisms drove long-term global climatic change during the early Eocene. This is one possible reading of the record of terrestrial CIE amplification across early Eocene hyperthermals and suggests that this record may embed valuable information on long-term changes in atmospheric $\rho CO_2$, but it is necessary to acknowledge that the interpretations derived here assume that other local, environmental influences on the terrestrial CIE magnitudes were similar in nature and proportional to event size across all of the hyperthermals.

Many other factors may potentially modulate the expression of the global hyperthermal CIEs in the Bighorn Basin pedogenic carbonate records, including changes in temperature effects on carbon isotope fractionation, changes in mixing ratios of atmospheric and organically derived CO$_2$ in soils, and changes in vegetation composition (Bowen et al., 2004; Smith et al., 2007). If each of these factors responded primarily to CO$_2$-driven hyperthermal global change then it is reasonable to assume a proportional, though perhaps nonlinear, magnitude of effect across the suite of events. Our data, however, suggest that at least one potential forcing factor for these effects, soil moisture, changed in a fundamentally different way during the PETM than during the four younger and smaller hyperthermals (Fig. 2). There is a clear indication of soil drying during the PETM-based soil development and chemical proxies in line with plant results (Kraus and Riggins, 2007; Kraus et al., 2013). The data presented here for the subsequent ETM2–I2 events show unchanged or slightly increased soil moisture levels.

Soil moisture, likely reflecting more general changes in local hydroclimate, would be expected to influence the soil carbonate CIE records through changes in the gas-phase permeability of the soil matrix (with wetter soils trapping more organically derived CO$_2$, leading to lower carbonate $\delta^{13}C$ values), influences on ecosystem productivity (with wetter soils supporting higher productivity, soil respiration, and lower $\delta^{13}C_c$), and changes in plant photosynthetic discrimination (with greater soil water availability increasing discrimination and reducing $\delta^{13}C_c$; Kohn et al., 2010; Diefendorf et al. 2010). Soil moisture differences between the PETM and younger hyperthermals could also have led to distinct plant community changes affecting the respective CIEs in pedogenic carbonate (Smith et al., 2007).

Evaluating just one of these potential changes, the reconstructed shift in precipitation inferred from PETM proxy data (a reduction in mean annual precipitation from ~1400 to ~900 mm year$^{-1}$; Kraus et al., 2013; this study) would, based on data documenting modern relationships between precipitation and photosynthetic discrimination (Kohn et al., 2010; Diefendorf et al., 2010), equate to a reduction in plant discrimination (and thus CIE$_{PETM}$) of ~0.9 to ~1.2‰. Our data suggest that changes in precipitation were negligible during the younger hyperthermals; thus, this effect could explain ~1‰ of the observed 5‰ PETM CIE$_c$ anomaly. Clearly this points to the need for a more comprehensive analysis including the effects of discordant local environmental changes on the expression of the global hyperthermal CIEs in soil carbonate records, but it also suggests that in many cases these effect sizes may be modest relative to those arising from $\rho CO_2$-driven changes in photosynthetic discrimination.

5 Conclusions

We recovered carbon isotope excursions of 2.4 and 1.6‰, respectively, related to the I1 and I2 events in floodplain sedimentary records from the Bighorn Basin, Wyoming. This adds to the three CIEs found earlier, the PETM, ETM2, and H2, underlining the sensitivity of these floodplain records for recording global atmospheric changes. Correlations with marine records and eccentricity forcing of hyperthermals corroborate the continuity of sedimentation that occurred in the basin starting above precession timescales of ~20 kyr. The 35 m short eccentricity-driven hyperthermal events are in line with precession forcing of the 7 m overbank–avalanche sedimentary cycles. Our CALMAG proxy-based soil moisture estimates reproduce similar or slightly enhanced soil moisture contents for the younger four hyperthermals, in contrast to reconstructions for the PETM. More environmental reconstructions, such as from vegetation, are needed for these four younger hyperthermals in the Bighorn Basin to confirm such a remarkable difference.
We find that the magnitudes of Bighorn Basin soil carbonate CIEs are linearly proportional to those recorded in benthic marine records for the post-PETM hyperthermals but that the soil carbonate CIE for the PETM is \( \sim 5\% \) smaller than expected based on extrapolation of the relationship observed for the other events. We show that the recently characterized dependence of photosynthetic \(^{13}C\) discrimination on atmospheric \( pCO_2 \) could explain this PETM excursion magnitude “anomaly” but would require substantially lower background (non-hyperthermal) \( pCO_2 \) conditions in the early Eocene than at the Paleocene–Eocene boundary. This would require reconciliation with globally increasing temperatures during this time interval. Local environmental effects, such as the proxy-inferred reduction in mean annual precipitation during the PETM, likely also modulated the expression of the global hyperthermal CIEs in the Bighorn Basin soil carbonate records. The record of terrestrial carbonate CIE amplification across the sequence of hyperthermals may embed information on million-year changes in early Eocene \( pCO_2 \). However, more likely, it records the influence of nonuniform local or regional environmental responses to these events, perhaps reflecting the crossing of a discrete climate system or ecological thresholds during the PETM that were not reached during the smaller, subsequent hyperthermals.
Appendix A

Nomenclature

- $a$: atmosphere
- $bkg$: background
- CIE: carbon isotope excursion
- CIE$_c$: CIE in paleosol carbonate
- $D$: difference
- $D\delta$: carbon isotope excursion magnitude
- $\Delta$: photosynthetic C-isotope discrimination
- $h$: non-PETM hyperthermal
- $p$: $pCO_2$
- $pCO_2$: atmospheric $CO_2$ pressure
- PETM: Paleocene Eocene Thermal Maximum
- ETM: Eocene Thermal Maximum
- $P$: pressure

Appendix B

Figure B1. Figure showing $p_{PETM}$ and change in PETM $pCO_2$ ($D_{pPETM}$) across a range of assumed background $pCO_2$ conditions from 250 to 3000 ppmv.
Information about the Supplement

Carbon isotope and soil bulk oxide results for the McCullough Peaks composite section.

The Supplement related to this article is available online at doi:10.5194/cp-12-1151-2016-supplement.
