Abstract. The Paleogene sedimentary records from southern China hold important clues to the impacts of the Cenozoic climate changes on low latitudes. However, although there are extensive Paleogene terrestrial archives and some contain abundant fossils in this region, few are accurately dated or have a temporal resolution adequate to decipher climate changes. Here, we present a detailed stratigraphic and paleomagnetic study of a fossiliferous late Paleogene succession in the Maoming Basin, Guangdong Province. The succession consists of oil shale of the Youganwo Formation (Fm) in the lower part and the overlying sandstone-dominated Huangniuling Fm in the upper part. Fossil records indicate that the age of the succession possibly spans the late Eocene to the Oligocene. Both the Youganwo Fm and the overlying Huangniuling Fm exhibit striking sedimentary rhythms, and spectral analysis of the depth series of magnetic susceptibility of the Youganwo Fm reveals dominant sedimentary cycles at orbital frequency bands. The transition from the Youganwo oil shale to the overlying Huangniuling sandstones is conformable and represents a major depositional environmental change at 33.88 Ma, coinciding with the Eocene–Oligocene climate transition (EOT) at ~33.7 to ~33.9 Ma. We suggest that the transition from a lacustrine to deltaic environment in the Maoming Basin represents terrestrial responses to the EOT and indicates prevailing drying conditions in low-latitude regions during the global cooling at EOT.

1 Introduction

The late Paleogene witnessed one of the most prominent climatic changes in the Cenozoic, a transition from greenhouse to icehouse world. The transition climaxed at the Eocene–Oligocene boundary when marine sediments registered a large, widespread, and rapid cooling in oceans (e.g., Zachos et al., 2001; Liu et al., 2009; Bohaty et al., 2012), which was accompanied by a sudden deepening of the carbonate compensation depth (CCD) by ~1.2 km (Pälike et al., 2012) in oceans and a calamity in the marine community that gave rise to the largest marine mass extinction since the end of Cretaceous (e.g., Prothero, 1994; Pearson et al., 2008; Cotton and Pearson, 2011). On land, this transition is expressed as rapid ice sheet growth over Antarctica (e.g., DeConto and Pollard, 2003; Coxall et al., 2005; Goldner et al., 2014) and largescale cooling (e.g., Zanazzi et al., 2007; Dupont-Nivet et al.,...
2 Geologic setting

The Maoming Basin is an intramontane basin situated in the southwestern part of Guangdong Province, southern China (Fig. 1). From the bottom to the top, the Cenozoic succession of the basin consists of the Shangdong Formation (Fm), Youganwo Fm, Huangniuling Fm, Shangcun Fm, Laohuling Fm, and Gaopengling Fm (BGMRGP, 1988, 1996). Among these units, the Eocene to Oligocene strata are found in the Youganwo Fm and the Huangniuling Fm (Fig. 2).

The Youganwo Fm is characterized by the occurrence of siltstones and shales containing coal seams in the lower part and the predominant occurrence of oil shales in the upper part (Fig. 2). The Youganwo Fm contains abundant vertebrate and plant fossils including the turtle species Anosteira maomingensis, Isometremys lacuna, and Adocus inexpectatus (Chow and Liu, 1955; Chow and Yeh, 1962; Claude et al., 2012; Danilov et al., 2013), the crocodile species Tomistoma petrollica and Alligatoridae (Yeh, 1958; Li, 1975; Skutschas et al., 2014), the fish species Cyprinus maomingensis (Liu, 1957), the mammalian species Lunania cf. L. youngi (Wang et al., 2007; Hren et al., 2013). While the transition is widely recognized in the marine realm (Zachos et al., 2001; Jovane et al., 2006; Liu et al., 2009; Pälike et al., 2012; Westerhold et al., 2014) and is increasingly well-defined in terrestrial records from the Atlantic region (e.g., Zanazzi et al., 2007; Hren et al., 2013), its impacts on the Asian environment remain poorly understood. This is largely because the concomitant tectonism, i.e., the Tibetan Plateau uplift, and the development of monsoonal climate may also have a strong influence on the Asian environment (e.g., Dupont-Nivet et al., 2007; Quan et al., 2012, 2014; Wang et al., 2013; Licht et al., 2014, 2015; Shukla et al., 2014).

There are numerous basins in southern China that host conspicuous Cenozoic sedimentary archives documenting the Cenozoic climate changes in the region. The late Paleogene sedimentary records from this region are of particular interest because they hold clues to the dramatic shift of climates in low-latitude Asia (Quan et al. 2012; Wang et al., 2013; Licht et al., 2014, 2015), where the influence of the Tibetan Plateau uplift should be minimal in comparison to the Asian interior. However, although abundant Paleogene sedimentary successions were developed here (e.g., Tong et al., 2005, 2013), their age controls are generally poor. Despite the fact that some successions contain vertebrate and/or plant fossils (e.g., Tong et al., 2005, 2013), their age ranges of these fossils are often too broad to date climate changes with satisfactory accuracy and precision.

In this paper, we present a detailed stratigraphic and paleomagnetic study on the fossiliferous Eocene to Oligocene succession in the Maoming Basin of Guangdong Province, southern China, to construct a new chronostratigraphic framework that is based on an integrated litho-, bio-, magneto-, and cyclostratigraphy. The new chronology not only greatly reduces the uncertainty but also significantly refines the available fossil-based timescale of the succession. In particular, the substantially refined chronology permits establishing the link between the dramatic environmental change in the basin and the global Eocene–Oligocene climatic transition and thus provides a critical chronological basis for further detailed examination of climate changes in this region.

Figure 2. Stratigraphy of the investigated section exposed in the now abandoned open mine pit in the Maoming Basin. Lithostratigraphic column (a) shows that the investigated section contains the Youganwo Fm and the overlying Huangniuling Fm. The stratigraphic column of the upper part of the Huangniuling Fm schematically shows the overall rhythmic sedimentary feature that is characterized by the repeated occurrence of a sedimentary package that is composed of a thin bed (shown in red lines) of red sandstone at the base, massive grey sandstone in the middle, and a light grey mudstone bed at the top. The Youganwo Fm also exhibits sedimentary rhythms that are characterized by repeated occurrence of the beds with distinct reddish color (shown in pinkish lines) visible from a distance. Sedimentary cycles (b) are reflected by magnetic susceptibility data. The distinct reddish beds in the Youganwo Fm and the thin red sandstone layers in the Huangniuling Fm generally correspond to the magnetic susceptibility peaks. The distinct thin red sandstone layer of a sedimentary package in the Huangniuling Fm is numbered and a total of 19 sedimentary packages are identified. Note the different scales of the magnetic susceptibility of the Youganwo Fm (the lower part) and the Huangniuling Fm (the upper part). Field photographs (c–e) show the major sedimentary features of the two formations and the contact between them. In (c), the red arrows indicate the red, thin marker bed of sandstone in the Huangniuling Fm. In (d), the arrow marks the contact between the two formations, displaying a continuous, gradual transition from brown grey mudstones in the uppermost section of the Youganwo Fm to pale grey mudstones at the base of the Huangniuling Fm. In (e), the yellow ellipse at the lower–middle part of the picture marks a person (~1.6 m) for scale; red arrows point to several distinctive reddish layers that form the sedimentary rhythms in the Youganwo Fm; “br grey”: brown grey; “lt grey”: light grey.
The age of the formation is controversial, with suggested dates varying from the Eocene to the Oligocene (e.g., Liu, 1957; Yeh, 1958; Yu and Wu, 1983). A comprehensive review of the fossil records suggests that the Youganwo Fm was most likely deposited in the late Eocene (Jin, 2008). The late Eocene age is interpreted to include both the Priabonian Stage and the Bartonian Stage of the Eocene based on recent advances in understanding fossil mammals of *Lunania*. Although the systematic position of the genus *Lunania* is still not fully understood, increasing evidence appears to constrain its age to the Bartonian to Priabonian Stage of the Eocene. To date, two species in total have been reported: *Lunania zhoui* from the Yuanqu Basin in central China (Huang, 2002) and *Lunania youngi* from Yunnan (Chow, 1957; Zong et al., 1996) and Maoming (Wang et al., 2007) in southern China. The geological age of *Lunania zhoui* is regarded to be no earlier than the Bartonian and no later than the Priabonian Stage (Tong et al., 2005).

For the *Lunania youngi* from Yunnan, it has been considered to date to the Bartonian to Priabonian stages (Li and Ting, 1983; Russell and Zhai, 1987; Wang, 1992; Qiu and Wang, 2007), to the Bartonian (Tong et al., 1995), to the early late Eocene (Huang and Qi, 1982), or to the end of the Eocene (Tong et al., 2005; Wang, 1997). Therefore, the late Eocene age of the mammal fossil in the Maoming Basin should be understood as including both the Priabonian Stage and the Bartonian Stage of the Eocene.

The overlying Huangniuling Fm consists mainly of sandstones and siltstones (Fig. 2). The lower part of the Huangniuling Fm is dominated by massive, pebbly coarse sandstones interbedded with thinly bedded, grey, silty mudstones. This formation contains plenty of plant macrofossils such as fruits and leaves (e.g., Feng et al., 2013). The age of the Huangniuling Fm has been ascribed to the late Eocene to Oligocene or even to the Miocene (Yu and Wu, 1983; Wang et al., 1994; Guo, 2006; Aleksandrova et al., 2012).

The areal extent of these two formations and other Cenozoic architectural units in the Maoming Basin was mapped by Guo (2006), who compiled stratigraphic data from drill cores and outcrops. Sedimentary facies analyses of these sedimentary units indicate that the alluvial fan and fan delta were initially developed in the northeastern part of the basin, which gradually gave rise to a lacustrine environment that expanded to the whole basin and alternated with a deltaic environment as the lake area grew and decreased again (Guo, 2006). Accordingly, successions that were accumulated in the lacustrine and deltaic environments often exhibit various subfacies and microfacies. For instance, subfacies and microfacies analysis indicates that the lower part of the Youganwo Fm was initially formed in a littoral zone or shallow-lake environment that was replaced by a prodelta environment and subsequently by a shallow-lake environment (Guo, 2006).

The oil shale that dominated the upper part of the Youganwo Fm was deposited mainly in semi-deep- or deep-lake environments that gave rise to a shallow-lake environment in the uppermost section of the Youganwo Fm. The Huangniuling Fm was deposited predominately in deltaic environments that vary from prodelta and delta front to delta plain environments (Guo, 2006). The uppermost part of the Huangniuling Fm, which mainly consists of muddy siltstone and mudstones, was deposited in a prodelta environment that transitioned to a shallow-lake environment where the younger Shangcun Fm was deposited.

A magnetostratigraphic study has previously been conducted in the Maoming Basin (Wang et al., 1994). The paleomagnetic data were collected from three different sites – drill cores MR and MB as well as an outcrop section MS (Fig. 1b) – and stratigraphic data from these three sites were compiled to obtain a composite stratigraphy that comprises the upper part of the Youganwo Fm, Huangniuling Fm, Shangcun Fm, and Laohuling Fm. The age of the composite stratigraphy was interpreted to span chron 18n to chron 12n (Wang et al., 1994). However, the magnetostratigraphy of Wang et al. (1994) can only be regarded as preliminary by modern standards because of the following reasons. The mean sampling spacing is large (~2.6 m). In addition, changes in sedimentation rates as indirectly reflected by the lithology were not taken into account. Furthermore, although samples of the Huangniuling Fm, Shangcun Fm, and Laohuling Fm were collected from the same core, i.e., the 874 m long MR core, samples of the Youganwo Fm were collected from both the MB core (15 samples) and the MS section (17 samples). The MB core is 567 m long, penetrates the Cenozoic strata, and reaches the Cretaceous rocks. No details were available as to how these 32 samples from two different sites were integrated to make a composite stratigraphy for the Youganwo Fm, particularly given that the MB core is relatively condensed and its base reaches the Cretaceous rocks. In particular, concerning the stratigraphic interval equivalent to that of this study, i.e., the upper Youganwo Fm and the lower Huangniuling Fm, the sampling spacing was on average about 6.0 m (Figs. 2 and 5 of Wang et al., 1994), which is too large by modern standards.

### 3 Methods

The study section is well exposed in the cliffs of the now abandoned open mine pit (21°42.3′N, 110°53.9′E), located to the northwest of Maoming City (Fig. 1). The exposed section comprises the upper part of the Youganwo Fm and the overlying Huangniuling Fm. In this study, the upper 31.5 m of the Youganwo Fm and the basal 30 m of the Huangniuling Fm were measured. Major lithological changes in the upper part of the Huangniuling Fm are noted. To detect subtle changes in the lithology of the exposed Youganwo Fm, magnetic susceptibility was measured with a handheld susceptibility meter, SM30, typically at every 10 to 20 cm. Spectral analysis of the depth magnetic susceptibility data series was performed using the technique of Muller and MacDon-

4 Results

4.1 Sedimentary rhythms

The lithostratigraphy of the investigated section is summarized in Fig. 2. From a distance, the lithology difference between the Youganwo Fm in the lower part and the Huangniuling Fm in the upper part of the section is indicated by the distinct color contrast (Fig. 2c–e). The overall light brownish color in the lower part characterizes the exposed Youganwo Fm, while the overall pale grey to light yellowish color in the upper part characterizes the overlying Huangniuling Fm (Fig. 2e). The investigated Youganwo Fm consists predominately of brown to dark brown oil shales, with faint thin laminations. Brown grey to grey mudstone occurs in the uppermost section of the Youganwo Fm. The overlying Huangniuling Fm contains dominantly massive sandstone and siltstone beds that are interbedded with pale grey to grey thin mudstone beds.

One of the most striking features of the outcrop is the occurrence of sedimentary rhythms, which are impressively expressed as the repeated occurrence of beds with a distinct reddish color in both the Youganwo Fm and the Huangniuling Fm (Fig. 2c, e). In the Youganwo Fm, there are more than
Figure 3. Spectral analysis of the depth series of magnetic susceptibility data of the Youganwo oil shale. The analysis reveals dominant sedimentary cycles with cycle wavelength ratios similar to periodicity ratios of orbital cycles, suggesting that these sedimentary cycles probably represent orbital cycles. The red curve represents the noise level above which the spectral peaks are considered statistically significant. The numbers above the spectral peaks indicate cycle wavelengths (in centimeters) of the sedimentary cycles. See text for details.

The sedimentary rhythm is particularly well expressed between ~11 and 30 m, where the average spacing between two neighboring reddish beds is about 1.0 to 1.5 m (Fig. 2a). Inspection of the beds with reddish color at the outcrop found that the reddish coloration only occurs at the surface and represents weathering banding of the beds because the fresh exposure of these beds does not show reddish color. Despite the fact that the reddish color represents recent weathering, not the depositional signature, weathering enhanced the expression of changes in lithology and made the subtle lithological changes more distinctly and strikingly visible on the outcrop. Because the reddish layers correspond to higher magnetic susceptibility values and less reddish levels display relatively lower magnetic susceptibility values, magnetic susceptibility data can facilitate the characterization of sedimentary cycles in the Youganwo Fm. Indeed, our high-resolution magnetic susceptibility data also exhibit meter-scale cyclicity (Fig. 2b). Spectral analysis of the magnetic susceptibility data reveals dominant sedimentary cycles with a cycle wavelength of ~252, 127 to 107, and ~30 cm (Fig. 3). The 127 to 107 cm cycle and the ~30 cm cycle have a cycle wavelength ratio of 3.6:1 to 4.2:1. The ~252 cm cycle and the 127 to 107 cm cycle have a cycle wavelength ratio ranging from 1.98:1 to 2.35:1.

The point of contact between the Youganwo Fm and the overlying Huangniuling Fm is abrupt at many locations around the edge of the open mine pit where the siltstone- and sandstone-dominated Huangniuling Fm sits directly atop of brown grey to dark grey mudstones of the upper part of the Youganwo Fm. However, when the contact is traced toward the center of the basin, the interface between the two formations is represented by a ~50 cm thick layer that displays a continuous, gradual change from brown grey mudstones in the uppermost section of Youganwo Fm to pale grey mudstones at the base of the Huangniuling Fm (Fig. 2d). Above the pale grey mudstone are siltstones and sandstones, exhibiting a coarsening upward trend in grain size. Further upsection, the siltstones and sandstones are interbedded with thin layers of pale grey mudstones in the lower part of the Huangniuling Fm.

In the Huangniuling Fm, sedimentary rhythms are indicated by the repeated occurrence of distinct red layers. The red layer occurs at the base of the pale grey massive coarse sandstone and is typically a few centimeters thick. The basal red sandstones are more resistant to weathering than the rest of the massive sandstones and commonly stick out of the surface of the outcrop, making the distinct red layers readily recognizable from a distance (Fig. 2c). The thickness of the massive sandstone varies largely from decimeters to meters, occasionally up to dekameters. Typically, there is a relatively thinner mudstone bed above massive sandstones (Fig. 2c). A red layer, massive sandstones, and a thin mudstone bed appear to form a parasequence that occurs repeatedly across the Huangniuling Fm (Fig. 2a, b, c). In the lower part of the Huangniuling Fm, the sandstone and mudstone beds in the parasequence are nearly flat and extend laterally with uniform thickness for hundreds of meters, and there is a fining-upward trend within a parasequence. In the upper part of the Huangniuling Fm, lens-shaped channelized sandstones are occasionally observed. Using the distinct red layer in a parasequence as a marker bed, we have counted 19 parasequences in the exposed Huangniuling Fm (Fig. 2a, b).

4.2 Rock magnetic data

4.2.1 Anisotropy of magnetic susceptibility (AMS)

The AMS data of the Youganwo samples show predominantly oblate fabrics with the minimum axes perpendicular to the bedding and the maximum and intermediate axes parallel or subparallel to the bedding (Fig. 4a, b). The degree of anisotropy (Pj) ranges from 1.0 to 1.232 (Fig. 4b). The AMS data of the Huangniuling samples display mainly oblate fabrics (Fig. 4d) but also show a weak prolate fabric with the maximum axes trending SE and the minimum and intermediate axes girdling along the NE–SW direction (Fig. 4c). In addition, the degree of anisotropy of the Huangniuling samples is low, varying from 1.0 to 1.089 and mostly below ~1.03 (Fig. 4d).
4.2.2 Temperature-dependence magnetic properties and IRM

Thermomagnetic curves of the samples show that all the low-field magnetic susceptibility values at the end of the experiments are higher than those at the beginning of the experiments, suggesting that transformation of magnetic mineral phases occurred during heating (Fig. 5a–e). Because the cooling curves generally show a rapid increase in susceptibility from 580 to 500°C (Fig. 5a–e), magnetite minerals were probably produced during the experiments, leading to elevated susceptibility values by the end of the experiments. The mudstone in the lower part of the Huangniuling Fm (Fig. 5a, b) and the brown grey shale of the uppermost Youganwo Fm (Fig. 5c) show overall similar features with an increase in magnetic susceptibility between 450 and 500°C during heating, whereas the oil shale samples show an increase in magnetic susceptibility at ~250°C and another major increase between 400 and 450°C (Fig. 5d, e) during heating. For the oil shale samples, the magnetic susceptibility increase at ~250°C (Fig. 5d, e) is diagnostic of hexagonal pyrrhotite due to thermally activated vacancy ordering (Dunlop and Özdemir, 1997), and the subsequent increase in magnetic susceptibility between 450°C and ~500°C probably indicates the transformation of pyrrhotite to magnetite during heating (Fig. 5d, e).

IRM acquisition of the samples shows that these samples are mostly saturated at fields above 200 mT (Fig. 5f). The demagnetization of IRMs in the backward DC fields suggests that the coercivity of the magnetic minerals is around 40 mT (Fig. 5f). The ZFC and FC low-temperature data of the samples show that the Huangniuling mudstone and the brown grey shale of the uppermost part of the Youganwo Fm exhibit similar features that are characterized by a small difference between the ZFC and FC curves (Fig. 5g, h). In addition, the Huangniuling mudstone shows a subdued transition at ca. 120 K (marked with an arrow in Fig. 5g), which may indicate the presence of magnetite (Verwey, 1939; Özdemir et al., 1993). Thermal demagnetization of the composite IRM of the Huangniuling mudstone and the brown grey shale of the Youganwo Fm shows that the low coercivity...
Figure 5. Rock magnetic data of samples from the Youganwo Fm and Huangniuling Fm. Panel (a–c): temperature dependence of magnetic susceptibility (MS) of samples from the Huangniuling mudstone (a, b) and from the uppermost brown grey shale (c) of the Youganwo Fm during a heating–cooling cycle between room temperature and 700 °C. Panel (f): IRM acquisition and the subsequent demagnetization in a backward DC field. Panel (g–j): zero-field-cooled (ZFC) and field-cooled (FC) low-temperature measurements of the representative samples. The arrow in (g) marks the subdued Verwey transition. Panel (k–o): thermal demagnetization of the composite IRM that was acquired along z, y, and x axes in a field of 1.2, 0.6, and 0.125 T, respectively.
civity component \((0.125 \, ^\circ \! T)\) unblocked at 580°C, confirming that magnetite is the major magnetic mineral phase in the Huangniuling mudstone and the brown grey shale of the uppermost of the Youganwo Fm. For the Youganwo oil shale, in addition to pyrrhotite, the presence of which is indicated by the rapid increase in magnetic susceptibility at \(\sim 250^\circ \! C\) (Fig. 5d, e), magnetite is present as well, which is evidenced by the 580°C unblocking temperature of the composite IRM (Fig. 5o). At some oil shale levels such as around 17.2 m, iron sulfide phases become predominant, which is indicated by the sharp drop in the composite IRM between 350 and 400°C (Fig. 5n). ZFC and FC low-temperature measurements show that there is a marked difference between the ZFC and FC curves (Fig. 5i, j), indicating the presence of pyrrhotite (Snowball and Torii, 1999). The \(\frac{M_r}{\chi}\) ratio of the Youganwo oil shale is typically around \(0.5 \times 10^{3}\) to \(1.0 \times 10^{3} \, \text{A} \cdot \text{m}^{-1}\), which is low in comparison to the \(\sim 70 \times 10^{3} \, \text{A} \cdot \text{m}^{-1}\) for greigite (Snowball and Thompson, 1990). Also, greigite tends to display little difference between ZFC and FC curves (Chang et al., 2007; Roberts et al., 2011). Therefore, greigite may not be present in Youganwo oil shale. Pyrrhotite is the dominant iron sulfide phase in the Youganwo oil shale and was likely produced during the oil shale accumulation.

### 4.3 Paleomagnetic data

Natural remanent magnetizations (NRM) of the samples range between \(3 \times 10^{-3}\) and \(20 \, \text{mA} \cdot \text{m}^{-1}\) with the majority being on the order of \(10^{-2}\) to \(10^{-1}\) \,\! mA \,\! m^{-1}. About half of the specimens are magnetically unstable, displaying erratic directions upon demagnetization. For the rest of the samples, the AF demagnetized samples generally show demagnetization trajectories decaying toward the origin (Fig. 6a, b, c) and the thermally demagnetized samples generally show relatively stable demagnetization trajectories below 400°C (Fig. 6d, e, f), above which erratic directions occur. For most samples, the linear segment of the demagnetization trajectory with coercivities \(> 15 \, \text{mT}\) or with a temperature range from \(\sim 150\) to \(\sim 340\) or \(380^\circ \! C\) that decays toward the origin is regarded as a characteristic remanence (ChRM). The demagnetization data together with the rock magnetic data (Sect. 4.2.2) suggest that the remanence of the samples mainly resides in magnetite, and pyrrhotite becomes the dominant magnetic mineral phase in the Youganwo oil shale.

To obtain reliable estimates of the ChRMs, the following criteria are also used to scrutinize the data: (a) we generally accept ChRMs of higher coercivity or unblocking temperature component decaying toward the origin with at least four data points; (b) ChRMs with a maximum angular deviation (MAD) greater than \(16^\circ\) are rejected; (c) if two samples from the same stratigraphic level yield similar ChRMs, the sample that has a better definition of the ChRM is used. Following the above treatments, we obtain reliable paleomagnetic data from 63 stratigraphic levels (see Table S1 in the Supplement).

Among these data, ChRMs from 46 stratigraphic levels have their corresponding virtual geomagnetic pole (VGP) within 45° of the mean of VGPs. These 46 ChRMs show both normal and reversed polarities (Fig. 7). A reversal test was performed and passed at 95% confidence level (class “C”; McFadden and McElhinny, 1990). Therefore, the quality of the 46 ChRMs is ranked as “A” and the remaining 17 ChRMs are ranked as “B” in quality. Changes in inclinations and VGP latitudes of these ChRMs with depth are shown in Fig. 8c, d.

### 5 Discussions

#### 5.1 Depositional environment

The history of depositional environmental changes in the Maoming Basin was summarized by Guo (2006). For the investigated section in this study, the upper part of the Youganwo oil shale was deposited in a semi-deep- or deep-lake environment that gradually transitioned to a shallow-lake environment in the uppermost section of the Youganwo Fm (Guo, 2006). The striking sedimentary rhythms are dominated by 127 to 107 cm cycles and 30 cm cycles, displaying a cycle wavelength ratio of 3.6 : 1 to 4.2 : 1, which is similar to the periodicity ratio of 4 : 1 for the long-eccentricity and the short-eccentricity cycles. The 252 cm cycle has a cycle wavelength about 2 times that of the 127 to 107 cm cycles, probably representing the harmonics of the 127 to 107 cm cycles. Therefore, the dominant sedimentary cycles are probably in the orbital frequency bands and the meter-scale cycles may represent the long-eccentricity cycle. Since the Youganwo oil shale was formed in a lacustrine environment (Guo, 2006), the repeated occurrence of such subtle lithological changes, as shown as the meter-scale sedimentary cycles, was probably related to fluctuating lake levels, which can cause subtle changes in deposition and thus in lithology. Fluctuations in the lake level in the Maoming Basin may have been modulated by orbital variations because the dominant sedimentary cycles appear to be in the orbital frequency bands, probably representing long- and short-eccentricity cycles. Orbital variations probably affected moisture conditions in this region, leading to wet–dry oscillations and thus fluctuations in the lake level. Relatively less or more organic matter may have been accumulated during low or high lake level periods, respectively, resulting in subtle cyclic lithological variations. The subtle lithological changes become distinctly displayed as striking sedimentary cycles on the outcrop upon weathering. The reddish beds probably correspond to depositions during low lake level periods when relatively less organic matter was accumulated.

The contact between the Youganwo Fm and the Huangniuling Fm shows gradual change from brown grey mudstones in the uppermost section of Youganwo Fm to the pale grey mudstone at the base of the Huangniuling Fm, which gradually transitions to siltstones and further to sandstones. These features suggest that the deposition was continuous at the
Figure 6. Representative demagnetization data of samples from the section studied. Open and closed squares indicate the vertical and horizontal components, respectively.

study site when the Maoming Basin experienced the transition from a shallow lacustrine environment, as represented by the upper part of the Youganwo Fm, to a prodelta environment, as represented by the lower part of the Huangniuling Fm (Guo, 2006), while the lake level was probably dropping.

For the lower part of the Huangniuling Fm, since the sandstone and mudstone beds in a parasequence are nearly flat and extend laterally with uniform thickness for hundreds of meters, the lower part of the Huangniuling Fm was likely deposited in a prodelta to delta front or an interdistributary bay environment. Given the gradual nature of the transition from the Youganwo Fm to the Huangniuling Fm, the repeated occurrence of the parasequence in the lower part of the Huangniuling Fm was probably associated with fluctuating lake levels that may have been forced by orbital variations as well. This notion of orbital forcing is supported by the persistent pattern of rhythmic occurrence of the parasequences. This notion is also strengthened by the demonstrated orbital forcing of the deposition in marine (e.g., the Eocene–Oligocene boundary GSSP section in Italy; Jovane et al., 2006) and lacustrine (e.g., the Green River Fm; Meyers, 2008) settings during a similar time interval. For the upper part of the Huangniuling Fm, the occasional occurrence of lens-shaped channelized sandstones suggests that delta front to delta plain deposits gradually became dominant in the upper section.

Figure 7. Characteristic remanent magnetization in stratigraphic coordinates. The solid and open symbols represent the lower and upper hemisphere projection, respectively. Dec: declination; Inc: inclination; a95: radius of cone at 95% confidence level; n: number of data points; all angles are in degrees.
5.2 Definition of magnetozones

Oil shales in the Youganwo Fm exhibit predominantly oblate AMS fabrics (Fig. 4), indicative of a depositional origin of the fabrics. Silty mudstone layers in the Huangniuling Fm also show mainly oblate AMS fabrics, and prolate fabrics occur as well, though weak. These features indicate that the depositional fabrics developed in the presence of currents flowing at a moderate speed (Tauxe, 1998), which is consistent with a deltaic depositional environment for the Huangniuling Fm. In addition, reversed polarities are present and a reversal test passed the confidence criteria (Sect. 4.3). Taken together, the occurrence of depositional fabrics, the presence of reversed polarities, and the passage of a reversal test suggest that the remanence is likely primary. Therefore, both the VGP latitudes and inclinations are used to define magnetozones of the investigated sections (Fig. 8e). Also, the definition of magnetozones is primarily based on the A-quality ChRM data, and the B-quality ChRM data are only used as a second-order constraint for intervals where A-quality data are sparse (Fig. 8c, d). In addition, a polarity zone is defined by at least two consecutive levels of similar polarities. Changes in inclinations and VGP latitudes with depth
are largely in concert, which allows us to define two reversed polarity zones (R1 and R2) and two main normal polarity zones (N1 and N2) (Fig. 8e). Of these magnetozones, N1 and R2 are better defined. N1 is defined as occurring between 32.2 and 51.0 m, and R2 is defined as occurring from 25.0 to 32.2 m (Fig. 8e). The section below 25.0 m is dominated by the normal polarities except at ~10 m, where isolated negative inclinations and VGP latitudes occur (Fig. 8c, d). Although these negative values do not occur at consecutive depths (Fig. 8c, d), the trend of a shift toward negative values in both inclinations and VGP latitudes is evident and is consistent, suggesting that a reversed polarity probably exists at ~10 m (Fig. 8e). This possible reversed polarity zone is tentatively defined as being between ~11.0 and ~8.5 m, and it separates the lower 25 m of the section into two short normal polarity zones, N2 and N3 (Fig. 8e).

5.3 Major constraints on a GPTS

The correlation of these magnetozones to the standard GPTS is not unique due to the lack of numerical ages serving as anchor points. However, several constraints exist for the investigated section. When these constraints are used collectively and in conjunction with the defined magnetozones (Fig. 8e), it is possible to establish a reliable polarity timescale for this section.

The major constraints are as follows. First, the oil shales studied contain abundant vertebrate and plant fossils (Chow and Liu, 1955; Liu, 1957; Yeh, 1958; Chow and Yeh, 1962; Li, 1975; Yu and Wu, 1983; Wang et al., 2007; Claude et al., 2012; Feng et al., 2012, 2013). In particular, the mammal fossil (Lunania cf. L. youngi) (Wang et al., 2007), which was unearthed from the studied oil shale of the Youganwo Fm, provides the most definite evidence for a late Eocene age (Wang et al., 2007; Jin et al., 2008). Accordingly, the Youganwo oil shale was formed sometime in the Priabonian Stage and/or Bartonian Stage of the Eocene, which may span magnetic chron C18r to C13r, i.e., from 41 to 34 Ma (Fig. 8f). Second, the marked difference in lithology of the Youganwo Fm and the Huangniuling Fm suggests a drastic difference in sediment accumulation rates. The sampled Youganwo Fm consists predominantly of brown oil shales, whereas the overlying Huangniuling Fm comprises dominantly massive, pebbly coarse sandstones and siltstones. Therefore, the sediment accumulation rates for the Huangniuling Fm were much higher than those for the Youganwo Fm. In addition, although organic matter and silt content decreases upsection and grey mudstones occur in the uppermost section of the Youganwo Fm, changes in lithology within the Youganwo Fm are subtle. This suggests that the sediment accumulation rates of the Youganwo Fm studied should not change drastically. Third, the deposition between the Youganwo and Huangniuling Fms is continuous. The contact between the two formations displays a continuous, gradual change from brown grey mudstones in the uppermost section of Youganwo Fm to pale grey mudstones at the base of the Huangniuling Fm within an interval of ~50 cm. In addition, siltstones and sandstones overlying the basal pale grey mudstone exhibit a coarsening upward trend in grain size, indicating a continuous deposition during the transition from the Youganwo Fm to the Huangniuling Fm. Fourth, the characteristic sedimentary cycles of the investigated section may also be used as an additional constraint. In fact, the occurrence of sedimentary cycles is not unique in the section studied. A marine succession of a similar age in Massignano, Italy, also displays striking limestone–marl cycles (Jovane et al., 2006). Cyclic lithologic patterns are also seen in the middle Eocene oil-shale-bearing lacustrine succession in the Mudurnu–Göynük Basin, Turkey (Ocakoğlu et al., 2012), the Eocene oil-shale-bearing Green River formation in the United States (Meyers, 2008), and other terrestrial records of similar ages in Asia (e.g., Dupont-Nivet et al., 2007; Xiao et al., 2010). All these lithologic cycles are attributed to orbital forcing and represent orbital cycles (Jovane et al., 2006; Dupont-Nivet et al., 2007; Meyers, 2008; Xiao et al., 2010; Ocakoğlu et al., 2012). The strong lithologic expression of orbital variations in both marine and terrestrial records, particularly those containing oil shales, from widespread regions of similar ages leads us to believe that the sedimentary cycles of the section studied probably represent orbital cycles as well. In particular, the spectral analysis of magnetic susceptibility depth series of the Youganwo Fm reveals dominant sedimentary cycles with a cycle wavelength ratio of ~4:1, suggesting that these sedimentary cycles may represent long- and short eccentricity cycles. Therefore, these lithologic cycles can be used as an additional, first-order constraint when establishing a timescale for the section studied. Based on the definition of the magnetozones (Fig. 8), there are ~3.5 sedimentary cycles in N1. Because a sedimentary cycle in the Huangniuling Fm is represented by a sequence of a red layer, massive sandstone, and a thin mudstone bed, a red layer may not be readily identified at ~40 m where the accompanying thin mudstone bed does occur (Fig. 8). Therefore, there are probably four sedimentary cycles in the N1 zone. Similarly, there are about three sedimentary cycles in the R2 zone and ~8.5 sedimentary cycles in the N2 zone (Fig. 8).

5.4 Construction of a GPTS

With the aforementioned four constraints, correlations between the four polarity zones (Fig. 8e) and the magnetochrons C18r to C13r (Fig. 8f) can be examined and unrealistic correlations can be rejected. Because polarity zones N1 and R2 are better defined than the other two polarity zones, correlation is thus found mainly between the N1 and R2 pair and the consecutive normal and reversed magnetochrons of the GPTS. To facilitate the analyses, the N2 zone is also used, but as a secondary constraint, in establishing the correlations. The results of correlations are summarized in Table 1. With the first-order constraint that the Youganwo oil shales
were formed in the late Eocene, i.e., from C18 to C13, six ensembles of correlations are possible (Table 1). Ensemble 1 correlates the N1 and R2 zones with C18n and C18r, respectively. Ensemble 2 correlates the N1 and R2 zones with C17n and C17r, respectively. Ensemble 3 relates N1 to C16n.2n and R2 to C16r. Ensemble 4 links N1 to C16n.1n, R2 to C16n.1r, and N2 to C16n.2n. In Ensemble 5, the N1 and R2 zones are correlated to C15n and C15r, respectively. Ensemble 6 correlates N1 to C15n and R2 to C13r. The quality of each correlation is assessed by examining whether and to what extent the above four constraints are met. The correlation that satisfies most or all of the constraints is preferred and is used to establish the magnetic polarity timescale for the investigated section. For instance, Ensemble 1 is rejected because this correlation would place the majority of the Youganwo oil shale section (N2–N3), where fauna fossils of late Eocene age were discovered, in the middle Eocene (Fig. 8e, f). Ensembles 2 and 3 are rejected on the grounds that the sedimentation rate for N1 in the coarse sandstones is slower than or similar to that of R2 in the oil shale, which violates the second constraint. Ensemble 4 is also rejected because the sedimentation rate for the upper part of the Youganwo Fm (R2) is almost 2 times that of the lower part of the Youganwo oil shale, which is incompatible with the subtle compositional change within the Youganwo Fm studied.

For Ensemble 5, assuming that C16n.1r was not captured, probably due to its relatively short duration, the N2 zone would correlate to C16n. Such a correlation yields a sedimentation rate of ~6.37 cm kyr⁻¹ for N1, ~1.75 cm kyr⁻¹ for R2, and ~1.51 cm kyr⁻¹ for N2 (Table 1). These sedimentation rates comply with the constraints specified in Sect. 5.2. However, the sedimentation rates of ~1.51 to 1.75 cm kyr⁻¹ are probably too fast for the investigated oil shale because oil shale in the Youganwo Fm was formed in a semi-deep- to deep-lake environment (Guo, 2006) and the lithology of the investigated interval of the Youganwo Fm is nearly monotonous, consisting of only oil shale. A pure shale unit represents a condensed time interval and should accumulate at very slow rates. Two securely dated organic-rich black shale intervals in the mid-Cretaceous could serve as a useful analog to the oil shale of the investigated section. The securely dated black shale unit at ~120 Ma is about 5 m thick and represents ~1270 kyr (Li et al., 2008), and it was thus accumulated at a rate of ~0.39 cm kyr⁻¹. Similarly, the sedimentation rates of the securely dated black shale unit at ~94 Ma (Sageman et al., 2006) are estimated to be ~0.37 to ~0.50 cm kyr⁻¹. In addition, the Ensemble 5 correlation would result in a duration of 295 kyr (C15n) for the N1 zone and 411 kyr for the R2 zone. Because there are ~4 and ~3 sedimentary cycles in the N1 zone and the R2 zone, respectively, the sedimentary cycle in the N1 zone and the R2 zone would represent a ~74 and ~137 kyr cycle, respectively. The ~137 kyr cycle in the R2 zone could be a result of modulation by short eccentricity of orbital variations. However, the ~70 kyr cycle in the N1 zone is not in the frequency band of orbital variations and its

Note: Ni, n/a: Ni, n/a; Correlation 1. a – the correlation is unrealistic and is rejected; b – the correlation leads to a drastic difference in sedimentation rates between the upper (R2) and lower (N2) part of the Youganwo Fm; c – the correlation results in a sedimentation rate for N1, ~1.75 cm kyr⁻¹, and the sedimentary cycle represents 382 kyr based on Correlation 1. “n/a” denotes “not applicable”; “x” indicates that the correlation is unrealistic and is rejected; “√” indicates acceptable correlations. Superscript a–e provide brief comments on why a correlation is rejected. Ni, n/a: Ni, n/a; Correlation 1. a – the correlation is unrealistic and is rejected; b – the correlation leads to a drastic difference in sedimentation rates between the upper (R2) and lower (N2) part of the Youganwo Fm; c – the correlation results in a sedimentation rate for N1, ~1.75 cm kyr⁻¹, and the sedimentary cycle represents 382 kyr based on Correlation 1. “n/a” denotes “not applicable”; “x” indicates that the correlation is unrealistic and is rejected; “√” indicates acceptable correlations.
origin is thus difficult to interpret. Therefore, Ensemble 5 is rejected as well.

Ensemble 6 satisfies the constraints on sedimentation rates for the Huangniuling Fm and the Youganwo Fm. Also, the sedimentation rates of 0.42 to 0.56 cm ky⁻¹ for the Youganwo Fm (Table 1) are compatible with those of the securely dated, organic-rich black shales in the mid-Cretaceous. Furthermore, this correlation would result in durations of the N1, R2, and N2 zones that are largely comparable to those estimated from sedimentary cycles. With the Ensemble 6 correlation, the N1, R2, and N2 zones would represent ~548, ~1294, and ~3334 kyr, respectively. Since the N1 zone contains about four sedimentary cycles (Fig. 8a, b), each cycle would represent a ~137 kyr cycle, which is similar to the short-eccentricity cycle E2 (95 to 125 kyr). Similarly, since there are about three sedimentary cycles in the R2 zone (Fig. 8a, b), each sedimentary cycle would represent a ~431 kyr cycle, which is similar to the long-eccentricity cycle E1 (405 to 413 kyr). As an additional check, the duration of the sedimentary cycles within the N2 zone is calculated. There are ~8.5 sedimentary cycles in the N2 zone representing ~3334 kyr, and thus each sedimentary cycle has a duration of 392 kyr, which is similar to the periodicity of long-eccentricity cycle E1. Therefore, the sedimentary cycles in the Youganwo Fm are consistently shown as representing the long-eccentricity cycles. It is reasonable that the sedimentary cycles in N1, i.e., Huangniuling Fm, represent short-eccentricity E2 and sedimentary cycles in R2 represent long-eccentricity E1 because the sedimentation rate of the Huangniuling Fm is much higher than that of the Youganwo Fm and orbital cycles with shorter durations can be recorded in the Huangniuling Fm. Indeed, among these six ensembles, only Ensemble 6 can yield periodicities of all the sedimentary cycles, which are from different parts of the section, in the orbital frequency band within uncertainties (Table 1). Thus, taken together, Ensemble 6 can satisfy different aspects of major constraints within uncertainties and thus is acceptable.

Analyses of the six possible correlations lead to a conclusion that only Ensemble 6 correlation offers the most realistic scenario. Therefore, the Ensemble 6 correlation is employed to establish a chronological framework for the section studied (Fig. 8e, f). With this chronological framework, the transition from the Youganwo Fm to the Huangniuling Fm took place within magnetochron C13r (Fig. 8). Because the transition is represented by a ~50 cm thick, mudstone-dominated interval and the C13n–C13r boundary (33.705 Ma) occurs at ~70 cm above the top of the transitional interval, the age of the onset of the transition can be determined by estimating the duration of the ~1.2 m thick interval. There are two ways to estimate the duration of the 1.2 m thick interval. One is to extrapolate the sedimentation rate of ~0.56 cm ky⁻¹ for the uppermost part of the Youganwo Fm, i.e., the R2 zone. This would lead to an estimate of ~210 kyr and the onset of the transition is then estimated to be at ~33.915 Ma. The second approach is to treat the 1.2 m thick interval as the upper part of the long-eccentricity cycle in the uppermost section of the Youganwo Fm (Fig. 8a, b). This results in an estimate of ~140 kyr for the 1.2 m thick interval and an onset age of ~33.845 Ma. Taking the average of the above two estimates, we obtain a mean age of 33.88 Ma for the onset of the transition. In summary, the constructed timescale represents a significantly refined chronology for the Paleogene strata in the Maoming Basin and provides the tightest possible constraints on the timing of the onset of the transition from a lacustrine environment to a deltaic environment in the Maoming Basin.

5.5 Paleoclimatic implications

The rapid transition from a lacustrine environment to a deltaic environment could be related to global climate change. In the late Paleogene, the Earth’s climate underwent a major transition from greenhouse to icehouse that climaxed at the Eocene–Oligocene boundary (Zachos et al., 2001). This climatic transition was accompanied by rapid ice sheet growth in Antarctica (e.g., DeConto and Pollard, 2003; Coxall et al., 2005; Goldner et al., 2014) and was characterized by pronounced global cooling (e.g., Zanazzi et al., 2007; Liu et al., 2009; Bohaty et al., 2012; Hren et al., 2013). The Eocene–Oligocene transition (EOT) was dated to 33.714 Ma (Jovane et al., 2006) from the marine succession in Massignano, Italy, which is the Global Stratotype Section and Point (GSSP) for the Eocene–Oligocene boundary. Studies of the equatorial Pacific records constrain the EOT to ~33.79 Ma (Pälike et al., 2006) or 33.89 Ma (Westerhold et al., 2014). The rapid transition from a lacustrine environment to a deltaic environment in the Maoming Basin is dated to 33.88 Ma, which coincides well with the timing of the EOT determined from marine records. The close timing suggests a strong link between the drastic environmental transition in the Maoming Basin and the EOT (Fig. 8f). The dramatic shift from a lacustrine to a deltaic environment in the Maoming Basin suggests that low-latitude Asia likely underwent a transition in regional hydrological cycle from humid to dry conditions in response to global cooling at the EOT. As dry conditions become prevalent, the lake level likely dropped and the lake area shrunk. The prevailing drying conditions together with global cooling during EOT probably promoted upland erosion and supplied abundant sediments to the shrinking lake, leading to the rapid increase in sediment accumulation rates after the dramatic environmental change. The dry conditions perhaps persisted in low-latitude Asia after the dramatic environmental change as the global climate continued to deteriorate following the rapid, severe, and widespread climatic transition at the Eocene–Oligocene boundary (Fig. 8f). This persistent dry condition is indicated by the accumulation of the sandstone-dominated Huangniuling Fm in the Maoming Basin at comparatively higher sedimentation rates. Indeed, similar depositional environmental change and an increase in sedimentation rates between 34.5
and 31 Ma are also observed in the Xining Basin and the EOT is considered as a possible cause (Dai et al., 2006).

The new, significantly refined chronology also indicates that the striking sedimentary cycles in both the Youganwo Fm and the Huangniuling Fm likely represent eccentricity cycles. The recognition of the eccentricity signal suggests that sedimentation in the Maoming Basin during this time interval may have been modulated by orbital variations, probably via lake level fluctuations at orbital frequency. The occurrence of eccentricity signals in the records is consistent with the fact the Maoming Basin is situated in the low-latitude areas that are sensitive to orbital variations at eccentricity frequency bands. Indeed, the modulation of orbital variations in sedimentation appeared to be widespread during this time interval. The long- and short-eccentricity signals are also detected from the Eocene–Oligocene Massignano section in Italy (Jovane et al., 2006). The eccentricity signals are also found in other marine successions (e.g., Westerhold et al., 2014) and lacustrine deposits (e.g., Meyers, 2008; Okacoğlu et al., 2012) of similar ages. Therefore, the drastic environmental change in the Maoming Basin during the EOT represents the terrestrial responses in low-latitude Asia to the EOT that may be superimposed on the long-term variations at orbital frequency. The investigated section in the Maoming Basin thus likely faithfully records the impacts of the EOT on low-latitude Asia.

Another notable feature is the different timings of the major lithologic changes in the Maoming terrestrial record and the marine record in Italy. In the GSSP section of Italy, the rapid lithologic change occurred at early stage of chron C13r, representing a precursor event of the EOT (Jovane et al., 2009) (Fig. 8i), while the main lithologic change in the Maoming Basin took place at the late stage of chron 13r, representing the major event of the EOT (Fig. 8a–f). This feature may indicate leads or lags of major environmental changes in the terrestrial and marine realms. The significantly refined chronology of the Maoming record from low-latitude Asia could potentially help us to better understand the teleconnection mechanism for the major global climatic transition across the Eocene–Oligocene boundary.

### 6 Conclusions

We have carried out a detailed stratigraphic and paleomagnetic investigation of the upper Paleogene succession in the Maoming Basin, southern China. The investigated succession comprises oil-shale-dominated Youganwo Fm and the overlying sandstone-dominated Huangniuling Fm. Both the Youganwo Fm and the overlying Huangniuling Fm exhibit striking sedimentary rhythms. The sedimentary rhythms of the Youganwo Fm are well expressed by the high-resolution magnetic susceptibility data, and spectral analysis of the magnetic susceptibility depth series reveals that the dominant meter-scale sedimentary cycles are in orbital frequency bands. The sedimentary rhythms in the Huangniuling Fm are characterized by the repeated occurrence of a parasequence containing a red sandstone layer, massive coarse sandstones, and a relatively thin mudstone bed. New paleomagnetic results, together with the lithologic and fossil age data, allow us to establish a magnetostratigraphy for the section studied that constrains the striking sedimentary cycles of the Youganwo Fm and Huangniuling Fm to long- and short-eccentricity cycles, respectively. Taken together, a significantly refined chronological framework is established for the investigated succession.

The contact between the Youganwo Fm and the Huangniuling Fm is represented by a 50 cm interval that shows a gradual change from dark grey mudstone in the uppermost section of the Youganwo Fm to the grey mudstone and siltstones with a coarsening upward trend in grain size at the base of the Huangniuling Fm. This interval represents a major environmental change from a lacustrine to a deltaic environment in the Maoming Basin, and its onset is dated to ~ 33.88 Ma. The timing of the onset of the dramatic environmental change is remarkably similar to that of the Eocene–Oligocene transition (EOT) that is dated to 33.7 to 33.9 Ma from various marine records. The synchronicity suggests a strong link between these two events and implies that the rapid environmental change in the Maoming Basin most likely represents terrestrial responses to the global cooling associated with the EOT. This notion is strengthened by the subsequent occurrence of the persistently prolonged dry conditions, as represented by the sandstone-dominated Huangniuling Fm, following the rapid environment change coincident with the EOT. These features are highly compatible with the continued deteriorating conditions after the EOT.

In addition, this study demonstrates that it is possible to construct a refined chronological framework for a terrestrial record by integrating multiple constraints synergistically from magnetostratigraphic, lithologic, biostratigraphic, and perhaps cyclostratigraphic data. For this study, six possible correlations between magnetozones and the standard GPTS are examined and accepted or rejected using four different types of constraints (Table 1). The robustness of the accepted correlation is thus dependent on how stringent and/or reliable these constraints are. In this study, although Ensemble 6 is considered as the most probable correlation after examining all six possible scenarios, constraints derived from the currently available data may not be stringent enough for a definite choice of Ensemble 6. For example, the repeated occurrence of parasequences in the upper part of the Huangniuling Fm has not been quantitatively assessed to show convincingly that these parasequences represent orbital cycles. Also, the difference in sedimentation rates of oil shale between Ensembles 5 and 6 – with the rate of Ensemble 5 being 2–3 times that of Ensemble 6 – may not be sufficiently large to differentiate between these two ensembles. Therefore, it would be beneficial to acquire more late Paleogene terrestrial records from other parts of low-latitude Asia in fu-
ture studies. It would also be interesting to test whether the major environmental change in low-latitude Asia truly coincides with the main EOT event or represents responses to a precursor event of EOT. Despite the limitations of the present study, the lack of detailed terrestrial records near the Eocene–Oligocene boundary in continental southeast Asia makes the results of this study an important contribution to the understanding of the impacts of the major climatic transition at the end of Eocene on the environment in low-latitude Asia.
