Abstract. While of higher plant origin, a specific source assignment of sedimentary leaf wax n-alkanes remains difficult. In addition, it is unknown how fast a changing catchment vegetation would be reflected in sedimentary leaf wax archives. In particular, for a quantitative interpretation of n-alkane C and H isotope ratios in terms of paleohydrological and paleoecological changes, a better understanding of transfer times and dominant sedimentary sources of leaf wax n-alkanes is required.

In this study we tested to what extent compositional changes in leaf wax n-alkanes can be linked to known vegetation changes by comparison with high-resolution palynological data from the same archive. We analyzed leaf wax n-alkane concentrations and distributions in decadal resolution from a sedimentary record from Trzechowskie paleolake (TRZ, northern Poland), covering the Late Glacial to early Holocene (13 360–9940 yr BP). As an additional source indicator of targeted n-alkanes, compound-specific carbon isotopic data have been generated in lower time resolution. The results indicated rapid responses of n-alkane distribution patterns coinciding with major climatic and paleoecological transitions. We found a shift towards higher average chain length (ACL) values at the Allerød–Younger Dryas (YD) transition between 12 680 and 12 600 yr BP, co-evaluated with a decreasing contribution of arboreal pollen (mainly Pinus and Betula) and a subsequently higher abundance of pollen derived from herbaceous plants (Poaceae, Cyperaceae, Artemisia), shrubs, and dwarf shrubs (Juniperus and Salix). The termination of the YD was characterized by a successive increase in n-alkane concentrations coinciding with a sharp decrease in ACL values between 11 580 and 11 490 yr BP, reflecting the expansion of woodland vegetation at the YD–Holocene transition. A gradual reversal to longer chain lengths after 11 200 yr BP, together with decreasing n-alkane concentrations, most likely reflects the early Holocene vegetation succession with a decline of Betula.

These results show that n-alkane distributions reflect vegetation changes and that a fast (i.e., subdecadal) signal transfer occurred. However, our data also indicate that a standard interpretation of directional changes in biomarker ratios remains difficult. Instead, responses such as changes in ACL need to be discussed in the context of other proxy data. In addition, we find that organic geochemical data integrate different ecological information compared to pollen, since some gymnosperm genera, such as Pinus, produce only a
very low amount of \( n \)-alkanes and for this reason their contribution may be largely absent from biomarker records. Our results demonstrate that a combination of palynological and \( n \)-alkane data can be used to infer the major sedimentary leaf wax sources and constrain leaf wax transport times from the plant source to the sedimentary sink and thus pave the way towards quantitative interpretation of compound-specific hydrogen isotope ratios for paleohydrological reconstructions.

1 Introduction

In the past decades organic geochemical proxies, such as concentrations and ratios of \( n \)-alkanes derived from aquatic and terrestrial organisms, have increasingly been used as palaeoecological indicators. These compounds have been postulated to be at least semi-source-specific for different groups of organisms, e.g., aquatic vs. terrestrial plants, trees vs. grasses, gymnosperms vs. angiosperms (e.g., Eglinton and Hamilton, 1967; Wakeham, 1976; Meyers and Ishiwatari, 1993; Ficken et al., 2000). Consequently, changes in \( n \)-alkane ratios in sedimentary records have frequently been interpreted to reflect changes in vegetation. Another important aspect is the variability of leaf wax concentrations, which appears to be high among different plants species (Diefendorf et al., 2011). This suggests that sedimentary \( n \)-alkanes rather reflect a signal biased towards strong leaf wax producers within the catchment instead of the average composition of vegetation. Finally, transit times from source to sink need to be considered. There is evidence for significant aging of leaf wax compounds, for example in soils, leading to potential lag times before deposition in sediments (Douglas et al., 2014; Gierga et al., 2016). These might differ from the transition times of plant pollen depending on the scale and type of the respective catchment (Feakins, 2013).

Here we focus on the transition from the Late Glacial to the Holocene, which was characterized by abrupt climatic and vegetation changes. After an initial warming phase (Bolling–Allerød) temperatures in western Europe rapidly dropped by ca. 4–6 °C for ca. 1100 years, possibly caused by a reduction of the northern Atlantic meridional overturning circulation (AMOC) forced by meltwater input into the North Atlantic (McManus et al., 2004; Rasmussen et al., 2006; Denton et al., 2010; Elmore and Wright, 2011; Heiri et al., 2014; Renssen et al., 2015). This Younger Dryas cold period (YD) was originally defined by means of ecological changes in Europe inferred from lacustrine palynological records (Firbas, 1949; Iversen, 1973; Overbeck, 1975). Attempts to precisely date the onset and termination of this event included the establishment of chronologies based on annually laminated (varved) sediments anchored by tephras and, such as the Laacher See Tephra (LST), Vedde Ash, Askja-S, or Hässeldalen (Brauer et al., 1999a, b; Goslar et al., 2000; Neugebauer et al., 2012; Lane et al., 2013; Wulf et al., 2013, 2016; Ott et al., 2016). For instance, by applying these techniques at Meerfelder Maar (MFM) in western Germany, the YD was dated to span from 12680–11590 yr BP (Brauer et al., 1999a, b). These studies have shown that vegetation changes in continental Europe at the YD onset were not synchronous with the cooling in Greenland (i.e., the onset of Greenland Stadial 1; GS-1) but occurred with a lag of ca. 100–170 years (Brauer et al., 1999; Lane et al., 2013; Rach et al., 2014). By reconstructing hydrological conditions in western Germany using compound-specific hydrogen isotope analysis of biomarkers in subdecadal resolution, Rach et al. (2014) suggested that aridification occurring ca. 170 years after the onset of the cooling in Greenland was the main trigger for the vegetation response. As a potential cause, they suggest the expansion of sea ice and a consequent southward migration of the westerlies, which then transported cooler and drier air to Europe (Brauer et al., 2008). Schenk et al. (2018) emphasized the importance of the Fennoscandian ice sheet as an additional influencing factor on wind dynamics in the North Atlantic realm. Recently, Słowinski et al. (2017) found a further slight delay (20 years) of the ecological changes at the YD onset in the more continental parts of eastern Europe compared to western Germany based on pollen data from Trzechowskie paleolake (TRZ), northern Poland. Constraints about the termination of the YD are less precise. While Rach et al. (2014) observed a synchronous start of the Holocene in the MFM compared to Greenland ice cores, there is an ongoing debate about the timing and nature of short-term cooling events, sometimes referred to as pre-boreal oscillation (PBO) during the early Holocene (e.g., Björk et al., 1997; Bos et al., 2007; Ott et al., 2016).

In this study we analyze a ca. 3000-year record from northern Poland, which spans from the Allerød to the early Holocene and was sampled in ca. 10-year resolution. The principal aim was to test to what extent leaf wax \( n \)-alkane compositional changes in lacustrine sediments can be linked to vegetation changes by comparison with published high-resolution palynological data from the same archive (Słowinski et al., 2017), which cover the Allerød to YD transition. Another goal was to evaluate possible differences in the transport pathways of pollen vs. leaf waxes, i.e., the identification of temporal leads or lags between leaf wax and pollen proxies. Further, we aim to establish a decadal, leaf-wax-based palaeoclimatological record over the time period of the YD.
2 Study site

The Trzechowskie paleolake (TRZ) is located in central northern Poland ca. 75 km SSW of the city of Gdańsk (TRZ; 53°52.40′ N, 18°12.930′ E; 110 m a.s.l.; Fig. 1) and developed after the retreat of the Late Weichselian ice sheet at ca. 15.8 cal kyr BP (Marks, 2012). It was formed by the successive melting of a buried ice block in a subglacial channel in the outwash plain of the Wda river and initially formed one large lake with still existing Lake Czechowskie (Słowiński, 2010; Błaszkiewicz et al., 2015; Słowiński et al., 2015). The paleolake maximum extension was approximately 1500 × 450 m before it turned into peatland (transition from gyttja to peat at depth 183–182 cm dated to 3050 ± 40 BP). Finally, in the late 19th century most of the former wetlands in this area were drained with the purpose of gaining agricultural grassland (Wulf et al., 2013; Słowiński et al., 2017). The present catchment is characterized by anthropogenic Pinus sylvestris forests. While spring and fall are characterized by alternating winds, major wind directions are low-speed westerlies during summers and easterlies during winters (Wós, 1999; Wulf et al., 2013). Mean annual precipitation and temperature are ca. 600 mm and 7 °C, respectively (1981–1998 period; Kozłowska-Szczesna, 1993; Wójcik and Marciniak, 1993).

3 Material and methods

3.1 Sampling and age model

A 137 cm long core section (1134–1271 cm of composite depth; Fig. 1b) was sampled in 0.5 cm intervals, except for the uppermost 17 cm and lowermost 10 cm, which were sampled in 1 cm intervals. Within the laminated section (1244.5–1262 cm), the sampling strategy was adjusted to obtain a 10-year resolution (i.e., sampling of 10 varves), resulting in sample slices varying between 0.4 and 0.7 cm of thicknesses.

The age model was created with OxCal v4.2 (Bronk Ramsey, 2001, 2008; Bronk Ramsey and Lee, 2013) using a P-sequence model with variable k parameter and the most recent radiocarbon calibration data set (IntCal13) (Reimer et al., 2013). The following age–anchor points have been used (Table 1): (a) five 14C AMS radiocarbon dates calibrated with the Intcal13 data set (Reimer et al., 2013); (b) two tephra layers (Askja-S: 1164 cm, 11 228 ± 226 yr BP, age from Ott et al., 2016; LST: 1253.75 cm, 12 880 ± 40 yr BP, age from Brauer et al., 1999b); (c) varve chronology within the laminated section anchored by the LST (Wulf et al., 2013); and (d) two biostratigraphic changes at the YD onset (termination) characterized by a decrease (increase) in Pinus together with an abrupt increase (decrease) in non-arboreal pollen (NAP) and Juniperus. The latter were synchronized with similar shifts in nearby Lake Gosciaz (1244 cm, 12 650 ± 70 yr BP; 1183.5 cm, 11 515 ± 35 yr BP; Litt et al., 2001), which are considered as the regional stratotype for the YD–Holocene boundary in northern Poland (Ralska-Jasiewiczowa et al., 1992; Litt et al., 2001; Ott et al., 2016).

The age model of this study (Fig. S1 in the Supplement) includes the Askja-S tephra and a biostratigraphic change (Ott et al., 2016) as additional early Holocene anchor points, resulting in a slightly different age model than published earlier by Słowiński et al. (2017). Pollen and macrofossil data from this paper were transferred to the updated age model. Since Słowiński et al. (2017) focused on a core section that covers the Allerød–YD transition (1230–1262 cm), offsets between the old and updated ages within that part of the core were minor, i.e., within the range of 5–15 years and restricted to the nonlaminated part at the YD onset (between 1230 and 1244.5 cm).

3.2 Biomarker extraction and quantification

After freeze-drying and grinding with a mortar, the sediments were extracted for two cycles of 15 min with dichloromethane–methanol (9:1) using a Dionex ASE 350 accelerated solvent extraction system at 100 °C and 75 bar. 5α-Androstane was spiked as an internal standard to the total lipid extract before the aliphatic fraction was eluted over silica gel (0.040–0.063 mesh) with n-hexane. The n-alkanes were separated and quantified relative to an internal standard using an Agilent 7890A gas chromatography (GC) instru-
**Table 1.** Age–anchor points used for age–depth calibration of the studied core section (Słowinski et al., 2017). LST: Laacher See Tephra. Age from Brauer et al. (1999a). Askja-S age from Ott et al. (2016). Biostratigraphic age at the YD–Holocene transition from Ralska-Jasiewiczowa et al. (1992) and Litt et al. (2001). Age–depth plot of the age model in Fig. S1 in the Supplement.

* Indicates omitted ages.

The equipment equipped with an Agilent 5975C Series mass selective detector (MSD) system and flame ionization detection (FID; Agilent 7683B Series). 1 µL of sample was injected onto a 30 m Restek DB-5 column (30 m, inner diameter 0.25 mm, film thickness 0.25 µm). Temperature was programmed from 70–320 °C at a rate of 12 °C min$^{-1}$ (held 15 min).

### 3.3 Compound-specific carbon isotope analysis

Compound-specific carbon isotopic values were measured using gas chromatography–isotope ratio mass spectrometry (GC-IRMS). We used a Thermo Scientific® trace gas chromatograph equipped with a Restek RTX-5 column (30 m, inner diameter 0.25 mm, film thickness 0.25 µm) and a split-splitless (SSL) injector operated in splitless mode with an evaporation temperature of 60 °C. The GC was connected via a GC isolink with a combustion furnace (1000 °C) and a ConFlo IV interface to a Delta V Plus isotope ratio mass spectrometer. Reference peaks of CO$_2$ bracket target compound peaks during the course of a GC-IRMS run. Two of these peaks were used for the standardization of the isotopic analysis, while the remainders were treated as unknowns to assess precision. The precision of these replicates was better than 0.6‰. Data were normalized to the Vienna Pee Dee Belemnite (VPBD) carbon isotopic scale by comparing them with an external standard containing 15 $n$-alkane compounds ($C_{16}$ to $C_{30}$ of known isotopic composition; A5 mix obtained from A. Schimmelmann, Indiana University, Bloomington). The root mean square error of replicate measurements of the standard across the course of analyses was below 0.7‰. Linearity of the IRMS system was monitored regularly by analyzing a B mix provided by A. Schimmelmann (i.e., $n$-alkanes with different concentrations). Samples were concentrated in order to achieve sufficient signal intensities of target compounds and only peaks within the linearity range (>1000 and >10 000 mV) were evaluated.
3.4 Alkane parameters and statistics

Alkane parameters have been calculated using the following equations.

Average chain length (ACL): $\Sigma(C_n \times n)/\Sigma(C_n)$; $C_n$: concentration of each $n$-alkane with $n$ carbon atoms.

Proxy for aquatic macrophytes ($P_{aq}$; Ficken et al., 2000):

$$P_{aq} = (nC_{23} + nC_{25})/(nC_{23} + nC_{25} + nC_{29} + nC_{31}).$$

Before calculating Pearson correlation coefficients (PCCs) between $n$-alkane and pollen data, data have been z-transformed. Both data sets, consisting of 76 ($n$-alkanes) and 65 (pollen) data points, respectively, were transferred to equidistant time series with 65 data points using the zoo and simecol packages in R Studio. PCCs were calculated in SPSS.

4 Results

Aliphatic lipids in the samples were dominated by odd-chain C23, C25, C27, C29, and C31 n-alkanes, with nC27 as the most abundant compound in all samples. The summed concentrations of these five compounds ranged between 3 and 263 $\mu$g (g dry weight)$^{-1}$ (d.w.). Highest concentrations were measured before ca. 12 600 yr BP and between ca. 11 300 and 10 400 yr BP (Fig. 2). The top of the studied core interval was marked by a 4 cm thick organic-rich layer (Fig. 1b), which was characterized by enhanced n-alkane concentrations but unchanged n-alkane patterns.

Throughout the record, we observed significant changes in the relative abundances of target compounds, resulting in pronounced shifts of related parameters such as ACL, $P_{aq}$, and n-alkane ratios nC27/(nC27 + nC29) and nC27/(nC27 + nC31)nC29/(nC29 + nC31). For instance, ACL significantly increased between ca. 12 680 and 12 600 and decreased between 11 580 and 11 490 yr BP. Minor oscillations of these indices were observed during the Allerød and early Holocene.

20 samples were analyzed for carbon isotope ratios (expressed as $\delta^{13}C$ values). These values were relatively constant (ca. $-33\%e$) for the nC31 alkane, while nC29 $\delta^{13}C$ values became slightly more positive (up to $-31.5\%e$) throughout the studied interval (12 650–11 200 yr BP). Other n-alkanes were characterized by increasing enrichment in $^{13}C$ (higher $\delta^{13}C$ values) with decreasing chain length between ca. 12 600 and 11 600 yr BP. The highest $\delta^{13}C$ values ($-28\%e$) were measured for nC23 at ca. 11 900 yr BP. Data for n-alkane concentrations and $\delta^{13}C$ values can be found in Tables S1 and S2 in the Supplement.

5 Discussion

5.1 Sources of n-alkanes

5.1.1 Potential and constraints of n-alkane-based proxies

Sedimentary leaf wax n-alkane sources can be broadly distinguished based on n-alkane chain length. Principally, mid-chain alkanes ($nC_{23}$ and $nC_{25}$) are mostly attributed to aquatic sources or Sphagnum species, while long-chain compounds can be derived from terrestrial plants or emergent macrophytes (Eglinton and Hamilton, 1967; Baas et al., 2000; Ficken et al., 2000). In addition, it has been postulated that nC31 is indicative of grasses as trees preferably synthesize nC27 and nC29 alkanes. Consequently, the ratios of these compounds, such as nC27 vs. nC31, have frequently been applied in sedimentary archives to infer ecological changes in lake catchments such as shifts from grassland to trees (Meyers and Ishiwatari, 1993; Schwark et al., 2002; Meyers, 2003).

Nevertheless, an increasing number of studies have indicated that alkane patterns of plants are heterogeneous and compound distributions often overlap. For example, in some environments so-called “aquatic” mid-chain compounds ($nC_{23}$ and $nC_{25}$) have been shown to be derived partly from terrestrial sources (Aichner et al., 2010a; Gao et al., 2011), while long-chain “terrestrial” compounds ($nC_{27}$ and $nC_{29}$) were derived mainly from aquatic sources (Liu et al., 2015). Further, compilations of global plant data sets clearly indicate that indices such as ACL and long-chain n-alkane ratios do not reliably reflect classes of terrestrial vegetation (Bush and McInerney, 2013). In addition, the sedimentary n-alkane pattern will be dominated by plants producing and delivering the largest amount of n-alkanes into the sedimentary sink. Based on a large-scale survey of different tree species, Diefendorf et al. (2011) found that angiosperms showed a tendency to produce higher concentrations of n-alkane leaf wax lipids compared to gymnosperms, a result later confirmed by Bush and McInerney (2013).

5.1.2 Carbon isotopes as source indicators

Source allocation of n-alkane homologues can also be inferred from their carbon isotope composition. For instance, in West African lakes with catchments dominated by C4 vegetation, only nC31 alkanes showed a C4 isotopic signal. In contrast, other long-chain n-alkanes carried a C3 plant signature (Garcin et al., 2014), likely resulting from higher n-alkane production in the few C3 trees in the lake catchment compared to the dominating C4 grasses. While no C4 plants were present in eastern Europe, aquatic plants are also characterized by more positive $\delta^{13}C$ values (Allen and Spence, 1981; Keeley and Sandquist, 1992; Ficken et al., 2000; Mead et al., 2005; Aichner et al., 2010a), and an aquatic origin of mid- and long-chain n-alkanes can be confirmed or rejected:
Figure 2. Concentrations of n-alkanes, average chain length (ACL), \( P_{aq} \), n-alkane ratios, and \( \delta^{13}C \) values plotted versus age. Red dotted lines mark occurrences of tephra layers Askja-S (A-S: 11 228 ± 226 yr BP) and the Laacher See Tephra (LST 12 880 ± 40 yr BP) and the biostratigraphic change at 1183.5 cm of depth (11 515 ± 35 yr BP). Black triangles mark \(^{14}C\) AMS ages. The pink shaded interval on the x axis illustrates the laminated core section.

The constant \( \delta^{13}C \) values of ca. \(-33\)‰ for \( nC_{31} \) and slightly more variable values for \( nC_{29} \) in our data set from TRZ paleolake suggest a stable terrestrial C\(_3\) vegetation source for these compounds (Meyers, and Ishiwatari, 1993; Meyer, 2003) during the study period. The \( ^{13}C \) enrichment in \( nC_{23} \), \( nC_{25} \), and \( nC_{27} \) during the YD could be explained by (a) a change in the sources of these compounds or (b) limited CO\(_2\) availability to potential aquatic sources. The latter could be induced by low atmospheric \( pCO_2 \) or by the establishment of diffusion barriers such as ice cover and/or a thickened boundary layer in stagnant water. CO\(_2\) limitation due to enhanced aquatic productivity, higher water temperature, salinity, or pH can be excluded (Street-Perrott et al., 2004; Aichner et al., 2010a, b). More positive \( \delta^{13}C \) values could also result from a reduced isotopic fractionation of terrestrial plants subjected to water stress (Farquhar, 1989), in particular during the YD.
when 8%–15% lower humidities have been reconstructed at MFM (Rach et al., 2014, 2017). On the other hand, all terrestrial plants would be affected by increased aridity, which should be reflected in all n-alkane homologues, contrary to our observations.

5.1.3 Comparison with palynological proxies

Mid-chain n-alkanes (nC23, nC25)

Concentrations of mid-chain-length compounds were low throughout the whole record. For instance, nC23 exceeds 10 µg/g d.w. only during some episodes in the Allerød (Fig. 2). Submerged aquatic macrophytes principally produce low amounts of pollen and mainly use vegetative strategies for reproduction. Consequently, very low concentrations of aquatic pollen have been counted in the sediment samples. However, macrofossil remains of submerged species Potamogeton and Chara have also been found only in low amounts in some samples from the Allerød and early YD (Fig. 3). This gives evidence that submerged aquatic species have been of low abundance and contributed little to sedimentary organic matter in TRZ throughout the studied time interval, with a somewhat higher proportional input during the Allerød and early YD. Low δ13C values, which vary between −33% and −28%, also indicate a primary terrestrial origin of mid-chain n-alkanes. Submerged macrophytes use 13C-enriched bicarbonate as a carbon source, especially when carbon is limited at highly productive stands, leading to δ13C values of n-alkanes that can reach up to −12% (Allen and Spence, 1981; Keeley and Sandquist, 1992; Aichner et al., 2010a, b). Hence, low δ13C values for mid-chain compounds as measured in TRZ either indicate (a) low productivity of submerged macrophytes and/or (b) a relatively high proportional contribution of terrestrial sources to nC23 and nC25. We conclude that these mid-chain compounds comprise a mixture of aquatic and terrestrial sources, especially during the YD and Holocene.

Long-chain n-alkanes (nC27, nC29, nC31)

To further elucidate plant sources of n-alkanes in the sediments of TRZ we compared our organic geochemical data to pollen and macrofossil spectra (Fig. 3; low-resolution pollen data from Wulf et al., 2013; decadal pollen–macrofossil data across the Allerød–YD transition from Słowinski et al., 2017; unpublished low-resolution macrofossil data from 12 400–10 000 yr BP). Based on these data, the YD was characterized by relatively low amounts of tree and shrub pollen, except for Juniperus, which expands after the YD onset, and enhanced proportional input from herbaceous plants (Poaceae, Cyperaceae, Artemisia, Chenopodiaceae). The arboreal communities during the Allerød and Holocene were dominated by Pinus. Relatively high amounts and percentages of pollen and macrofossils derived from Betula sp. were mainly observed in samples from the YD to Holocene transition and also in samples from the early Allerød (Figs. 3 and 4).

From the aliphatic compounds in TRZ, the nC27 alkane shows the largest variability in concentration, which ranges from <10 µg/g d.w. during the YD up to >100 µg/g d.w. during the Allerød. This seems to reflect the trend of a contribution of arboreal pollen, specifically from Betula, to the lake sediments (Figs. 3 and 7). Leaf waxes of the gymnosperm tree species Pinus sylvestris have been shown to often contain high relative abundances of nC27 alkanes, but absolute concentrations are in most cases very low (Maffei et al., 2004; Ali et al., 2005; Dove and Mayes, 2005; Diefendorf et al., 2011; Bush and McInerney, 2013). It is therefore likely that Pinus does not contribute significant amounts of n-alkanes to the sedimentary archive of TRZ. On the other hand, Betula sp. as the second most abundant tree genera in the lake catchment could have been a major contributor to the sedimentary nC27 pool (Schwark et al., 2002; Diefendorf et al., 2011) and likely biosynthesizes higher absolute amounts compared to Pinus. Comparing palynological abundances and nC27 concentration data supports this idea. The high concentrations of nC27 alkanes during the early Allerød, between ca. 13 250 and 13 100 yr BP, coincide with an interval characterized by a dominance of Betula over Pinus (Wulf et al., 2013). Further, the increasing concentrations of nC27 between ca. 11 700 and 11 500 yr BP were in phase with Betula expansion at the YD–Holocene transition (Fig. 3). Finally, the expansion of Pinus after the onset of the Holocene was not reflected in increasing nC27 concentrations; rather, a decrease in n-alkane concentrations was observed. This decrease could be explained by a synchronous decrease in absolute and relative Betula abundances. Based on the covariation of nC27 concentrations and palynological data we consider Betula sp. as a dominant contributor to this compound, while Pinus sylvestris appears to be a less relevant source.

Another gymnosperm shrub species, Juniperus communis, was expanding during the early YD, peaking between ca. 12 300 and 12 500 yr BP, before gradually declining (Fig. 3; Wulf et al., 2013; Słowinski et al., 2017). Reported n-alkane concentrations for this species ranged from very low (Maffei et al., 2004) to high (Mayes et al., 1994). In the study of Diefendorf et al. (2011), Juniperus osteosperma was the only analyzed gymnosperm that showed intermediate concentrations of n-alkanes. All these studies reported that Juniperus sp. biosynthesizes relatively long chain lengths, in the range C31–C35, a pattern which has also been observed in plant samples from Lake Steisslingen (southern Germany; Schwark et al., 2002). This suggests that Juniperus sp. could be a significant contributor to nC31 also in the TRZ sediments, especially during the early YD. During phases of high nC31 abundance in the Allerød and Holocene other contributors must have been predominant.

Herbaceous plants could theoretically contribute to all measured n-alkanes, but have often been associated with a
dominance of longer n-alkane chain lengths (e.g., Maffei, 1994, 1996a, b; Zhang et al., 2004; Rommerskirchen et al., 2006). In TRZ, grasses and other herb pollen showed varying concentrations, with a tendency of higher amounts during the YD. Their proportional contribution significantly increased or decreased at the YD onset or termination, which was enhanced by the strong decline of tree pollen during the cold interval. We assume that these types of plants could indeed be strong contributors to the longer chain lengths, i.e., nC29 and nC31, specifically during the YD when concentrations of those compounds approach values of the dominating nC27 alkane. A proportional contribution from trees cannot be fully excluded, especially during the abovementioned phase of Juniperus expansion (early YD) as well as during parts of the early Holocene and Allerød when Betula was dominating.

Considering emergent aquatic and telmatic species, macrofossils were counted for species such as Typha lati-
Figure 4. High-resolution palynological data from the Allerød and transition into the YD in comparison to concentration of $n$-alkanes, ACL, and the $C_{27}/(C_{27} + C_{31})$ $n$-alkane ratio. The light grey shaded period indicates the transition from the Allerød to the YD (12 680–12 620 yr BP) as defined by Słowinski et al. (2017), while the dark grey shaded interval marks the YD. NGRIP ice core stratification according to Rasmussen et al. (2014). $\Sigma$herbs: NAP without Poaceae and Cyperaceae.

**Statistical correlation across the Allerød–YD transition**

To analyze possible correlations between occurrences of alkanes with vegetation more in detail, we compared \(n\)-alkane concentrations throughout the Allerød and transition into the YD (ca. 13 350–12 400 yr BP) with high-resolution pollen data from the same interval (Figs. 4 and 5). For the latter, data published in Słowinski et al. (2017; 1230–1262 cm) have been complemented by further unpublished data extending further into the Allerød (1262–1271 cm). Macrofossils have been excluded from this survey (a) due to lower sampling resolution (1 vs. 0.5 cm for organic geochemical proxies) compared to pollen and organic geochemical data and (b) as macrofossil samples were not taken from the same core.

We found that AP counts as well as some herbaceous plants and ferns showed a significant positive correlation with concentrations of \(C_{25}, C_{27}, \text{ and } C_{29}\) \(n\)-alkanes. In contrast, \(nC_{31}\) concentrations showed a significant correlation with NAP counts, but also with Salix. Significant correlations are also found between \(n\)-alkane concentrations and algae (Botryococcus, Pediasstrum) since the latter have been found in relatively high concentrations during the Allerød. Since *Botryococcus* does not produce \(n\)-alkanes (Lichtfouse et al., 1994), this could well be considered as an autocorrelation. It has to be noted that concentrations of \(n\)-alkane homologues strongly correlated with one other (Table S3 in the Supplement). This autocorrelation is due to the fact that basically all \(n\)-alkanes showed the same rough trend with high concentrations during the Allerød and low concentrations during the YD. Autocorrelations could also be found within pollen data; e.g., *Pinus* counts significantly correlated with *Betula* (*R = 0.79; p < 0.01; Table S4 in the Supplement). Hence, significant correlation does not necessarily indicate origin of \(n\)-alkanes but could be due to intercorrelations between concentrations of source organisms, which is specifically relevant for negative correlations. Principally,
the correlation coefficients reflect the major trends of pollen counts and n-alkane concentrations throughout the Allerød–YD transition. Significant positive correlations indicated that the pollen counts follow the rough trend of n-alkanes, i.e., high concentrations during the Allerød, low concentrations during the YD. In contrast, significant negative correlations suggested opposite trends, as relevant for Juniperus and some herbs (Artemisia, Chenopodiaceae, Helianthemum).

We conclude that compounds can be attributed to arboreal and non-arboreal sources. Comparison with pollen data suggest that the abundances of Betula and Juniperus in the catchment have had a strong impact on n-alkane concentrations and the composition of n-alkanes in TRZ sediments. Decreasing concentrations of mid-chain compounds, which are often interpreted as of aquatic origin, are here rather a mixture of aquatic and terrestrial sources, with high proportional input of the latter during certain time periods (see above).

Leads and lags between n-alkanes and pollen

Potential pre-aging of leaf waxes, i.e., residence time in soils before being deposited in sediments, has been a recent matter of debate. Some studies have shown that significant lag times occur before compounds are deposited in sediments, mainly due to long residence time in soils and transport via rivers as well as mixing processes (Eglinton et al., 1997; Uchikawa et al., 2008; Kusch et al., 2010). This is specifically the case for marine sediments but has recently also been shown for lacustrine systems by Douglas et al. (2014). Those authors quantified pre-aging of plant waxes from several hundreds to thousands of years in a warm and humid environment, in which transport times are expected to be low due to high rainfall and runoff. In contrast, Lane et al. (2016) inferred very short lag times for another tropical lake characterized by a small catchment area.

In TRZ we do not observe significant offsets between pollen and n-alkane signals neither at the YD onset nor during the termination (Figs. 3, 4, and 7). Especially the data at the YD onset show the most pronounced change in integrative n-alkane proxies between 12 680 and 12 620 kyr BP. This is precisely the time interval defined by Słowinski et al. (2017) as the transition phase between the Allerød and the YD (Fig. 4) based on decadally resolved pollen data. We conclude that leaf waxes experience very short transit times (i.e., subdecadal) before being deposited to the sediments in this small catchment system. We suggest that the major transport pathway of leaf waxes into the sedimentary record in this temperate system is due to direct litterfall into the lake during autumn, when trees shed their leaves.

5.2 Potential of n-alkane ratios as paleoecological proxies in TRZ

Downcore changes in proxies based on proportional contribution of specific n-alkanes (e.g., Paq, ACL, n-alkane ratios such as nC27/nC31) have frequently been applied to decipher paleoecological changes. Nevertheless, due to the abovementioned constraints, the applicability of alkane ratios as source indicators has been questioned, acknowledging that a uniform interpretation of proxies such as ACL is not possible (Rao et al., 2011; Bush and McInerney, 2013; Hoffmann et al., 2013). Our data illustrate that vegetation changes co-occurred with compositional changes in sedimentary n-alkanes and we argue that if constraints from other proxy data can be made, specific additional information can be derived from such proxies.

To test their applicability in our study area we correlated standard n-alkane ratios with pollen percentages during the interval 13 350–12 400 yr BP (Allerød–YD transition) (Fig. 6), when the strongest changes occurred. Positive correlations were found between n-alkane ratios and arboreal pollen from Pinus and Betula. The same ratios showed negative correlations to non-arboreal pollen (NAP) and arboreal pollen (AP) from Juniperus and Salix. The highest positive PCC was given by the ratio nC27/(nC27 + nC31) versus percentage of ΣAP excluding Juniperus and Salix (R = 0.81, p <0.001; Fig. 6). The same ratio also delivered the most negative coefficients for correlations versus relative amounts of NAP, grasses, herbs, Juniperus, and Salix. Slightly lower correlations were found for the ratio (nC27 + nC29)/(nC27 + nC29 + nC31), but principally all the analyzed ratios were good indicators to express changes in vegetation. Interestingly, the ratio nC29/(nC29 + nC31) strongly correlated with percentages of Betula (R = 0.80, p <0.001; Fig. 6), which is considered as a major nC27 producer. Given the discussion of sources of the compounds above, this could indicate that this proxy is useful to assess the proportional contribution of Betula to long-chain n-alkanes C29 and C31.

Similar to pollen vs. n-alkane concentrations, autocorrelations need to be considered when interpreting n-alkane-based proxies. For instance, if the aquatic contribution to the sediment is low as in TRZ, then the Paq must not be interpreted as a measure for aquatic influx but instead as an alternative expression for ACL, which explains the similarity of both curves (Fig. 2).

Although an exact assignment to sources was difficult, significant changes in n-alkane ratios mirrored shifts of pollen percentages throughout the YD onset. Therefore, we consider alkane ratios to be a good indicator for major ecological changes in the lake catchment. We suggest that a shift towards longer chain lengths at the YD onset (reflected by higher ACL and by long-chain alkane ratios) was indicative of a shift of a more tree-dominated catchment (Pinus–Betula communities, Wulf et al., 2013) to a higher abundance of herbaceous plants, complemented by shrubs Juniperus and Salix.
5.3 Paleoecological and climatic context

During the Allerød, i.e., between 13 360 and 12 680 yr BP, an average ACL of ca. 26.9 reflects the vegetation communities consisting of Pinus and Betula forests (Fig. 7). Shifts towards longer chain lengths (> 27.4) occurred between ca. 13 220–13 050 and 12 970–12 850 yr BP. Climatic variations during the Allerød were detected in numerous paleoclimatic records. The most recent chronology from NGRIP ice cores dated the Greenland interstadial cooling phase 1b (GI-1b) to 13 261 ± 149 to 13 049 ± 143 yr BP (Rasmussen et al., 2014; Fig. 5). This episode has been suggested to be equivalent to the “Gerzensee oscillation”, which has been observed in lake sediment records (von Grafenstein et al., 1999, 2000). In our record the ACL reversal between ca. 13 220 and 13 050 yr BP could probably be considered as a response of vegetation in the TRZ catchment to this cold oscillation, but the synchronicity of events could not be fully confirmed due to larger uncertainties of the age model in the non-varved section of the record. Another minor and short-term cooling reversal ca. 40 years before the onset of the YD, at around 12 720 yr BP, has recently been proposed for MFM (Engels et al., 2016) but was not clearly recorded by n-alkane ratios in TRZ because of the insufficient time resolution of our data.

The sharpest and most pronounced decrease in ACL was measured between 12 680 and 12 600 yr BP. This was synchronous with the transition phase of major vegetation changes as inferred from palynological data between 12 680 and 12 620 yr BP (Słowinski et al., 2017). No pronounced lag time for organic biomarkers, for instance due to prolonged residence time in soils or transport from the catchment to the lake, was observed. Given the precise age control in this varved and tephrochronologically anchored section of the record, the rapid vegetation change marking the YD onset appeared to be delayed by ca. 170 years compared to the onset of cooling as inferred from Greenland ice cores (GS-1 onset 12 846 ± 138 yr BP; Rasmussen et al., 2014), similarly as suggested for more westerly locations such as MFM (Rach et al., 2014). While the combined absolute dating uncertainty of both records (NGRIP and MFM) exceeds this delay, the relative age uncertainty in this section is much lower, evidenced by the common occurrence of the Vedde Ash isochron in MFM and NGRIP with a relative age difference of only 19 years (Lane et al., 2013; Rach et al., 2014) when based on their independent age models. The TRZ record can be linked...
to NGRIP indirectly through MFM, with which it shares the LST at 12,880 yr BP (Wulf et al., 2013; Brauer et al., 1999a, b, 2011), resulting in similarly low relative age uncertainties, at least in the varved core section.

Within the YD cold interval, the ACL was showing a gradual trend towards lower values. While some potential contributors to longer chain lengths such as Poaceae, Cyperaceae, and other herbaceous plants showed relatively constant pollen counts during the YD, some others such as Juniperus were more abundant during the first half of the YD (Wulf et al., 2013; Figs. 3 and 7). This is in agreement with the principal trend of $\delta^{18}$O values and Ca$^{2+}$ concentrations.
in Greenland ice cores, which indicated the coldest and driest conditions in the earlier phase of the YD, followed by a gradual and slight warming (Rasmussen et al., 2014). A similar pattern was also detected within proxy data from other European lakes, for example MFM (varve thickness, elemental composition, and $\delta^{13}D$ values; Brauer et al., 1999a, b; Rach et al., 2014), Ammersee ($\delta^{18}O$; von Grafenstein et al., 2003), paleolake Rehwiese (varve thickness; Neugebauer et al., 2012), and Lake Kråkenes (elemental composition; Lane et al., 2013; Fig. 7). Recently this bipartitioning of the YD was also observed in Lake Suigetsu (Schlolaut et al., 2017). Explanations for this phenomenon have been related to a re-strengthening of the AMOC at ca. 12 300 yr BP. Its slowdown and the consequent southward shifting of the polar front are considered as major triggers for the YD in Europe (McManus et al., 2004; Bakke et al., 2009; Elmore and Wright, 2011). The gradual strengthening of the AMOC pushed the polar front back to the north, which is the reason that the partially rapid climatic responses occurred earlier at more southern (ca. 12 240 yr BP at MFM) compared to more northern locations (ca. 12 140 yr BP at Lake Kråkenes) (Brauer et al., 2008; Lane et al., 2013). At TRZ, ACL, as an integrative proxy, showed shifts at ca. 12 300–12 280 and 12 200–12 190 yr BP, but changes were gradual and did not allow for a distinct identification of the timing of this climatic change. An explanation for this could be the continental setting of our study area, which showed weaker climatic responses compared to locations with stronger Atlantic influence (Slowinski et al., 2017).

The succession of n-alkane abundances between ca. 11 540 and 11 200 yr BP reflects the gradual expansion of vegetation around the YD–Holocene transition (defined by means of biostratigraphy at 11 515 ± 35 yr BP; Table 1) and during the early Holocene. An increase in $n_{27}$C concentrations starting around 11 540 yr BP, while $n_{31}$C reached the lowest concentrations within the studied interval, was possibly caused by expansion of Betula and triggered a sharp decrease in ACL between 11 580 and 11 490 yr BP. This shift occurred ca. 70–80 years earlier compared to the defined onset of the Holocene in Greenland at 11 654 ± 4 yr BP based on oxygen isotopes in the NGRIP ice core (Rasmussen et al., 2014). Due to age uncertainties between 35 and 90 years within the respective section of the TRZ record, ultimate quantification of the lag was not possible in this case.

A sudden increase in $n_{29}$C and $n_{31}$C concentrations at ca. 11 430 yr BP (Fig. 2), i.e., 90 years after the start of increasing $n_{27}$C concentration, was associated with a ca. 180-year reversal of ACL and n-alkane ratios, whose start was in phase with a cold period in Greenland referred to as the 11.4 kyr event (Rasmussen et al., 2014). In contrast to the YD, which was characterized by low concentrations of n-alkanes, the increasing ACL at 11.5 kyr BP was triggered by an increase in concentrations of long-chain compounds. It is likely that the rapid ecological developments in the lake catchment in the course of warming, such as expansion of forest vegetation and development of soils, were the main drivers behind the observed shift and not a response to a cooling within the catchment.

Cold reversals during the early Holocene are mostly referred to as pre-boreal oscillations (PBOs) and have been inferred from different proxies in many European lakes. The exact timing and possible synchronicity of these oscillations is still a matter of debate and PBOs are generally difficult to detect in lake sediments (e.g., Björk et al., 1997; Bos et al., 2007). Based on sedimentary analysis of a lake in southern Sweden, Wohlfahrt et al. (2006) suggested a PBO could be stratigraphically located between tephra layers Hässeldalen and Askja-S, which have been dated to 11 380 ± 216 and 11 228 ± 226, respectively (Ott et al., 2016). The fact that the decrease in ACL in the TRZ sediment core was observed ca. 10 cm below the Askja-S layer is evidence against a connection to the oscillation, at least according to the stratigraphic boundaries suggested by Wohlfahrt et al. (2006).

The upper 31 cm of the studied core interval covered the early Holocene from ca. 10 970 to 9940 yr BP at relatively low resolution due to lower sedimentation rates and increased sample size. This episode was characterized by a gradual change in n-alkane ratios, e.g., an increase in ACL, indicating the gradual establishment of Holocene vegetation in the lake catchment due to further gradual warming. Specifically after ca. 10 600 yr BP, a decrease in mainly $n_{27}$C alkane concentrations probably indicated a decline of Betula and further expansion of Pinus sylvestris as dominating species (Wulf et al., 2013).

6 Conclusion

The YD cold interval was characterized by relatively low concentrations of n-alkanes and pronounced changes in their relative abundances, which resulted in significant changes in n-alkane-based proxies. The shift towards higher ACL at the Allerød–YD transition between 12 680 and 12 600 yr BP was in phase with a lower contribution of tree pollen (Pinus and Betula) to the sediments and a subsequently higher abundance of pollen derived from herbaceous plants (Poaceae, Cyperaceae, and Artemisia), as well as shrubs (Juniperus and Salix). These major vegetation changes occurred ca. 170 years after the start of $\delta^{18}O$ decrease (GS-1 onset 12 846 ± 138 yr BP) in Greenland ice cores. The YD–Holocene transition was characterized by a gradual increase in $n_{27}$C concentrations starting at ca. 11 540–11 530 yr BP, most likely induced by an expansion of Betula and a sharp increase in $n_{29}$C and $n_{31}$C concentrations ca. 90 years later. Due to larger age uncertainties in the nonlaminated section of the core, these ecological changes were more difficult to place into context with the major warming in Greenland (11 654 ± 4 yr BP).

Short-term reversals of ACL and n-alkane ratios during the Allerød could possibly be linked to GI-1b, while a sim-
ilar pattern during the early Holocene was more likely trig-
gerred by rapid ecological responses in the course of warm-
ing. These results show that there is no standard interpre-
tation of changing proxy values. Instead, responses such as
changes in ACL need to be discussed under careful evalu-
ation of the parameters leading to the observed changes. Tak-
ing our studied interval, the major identified shifts towards
longer chain lengths (i.e., during the Allerød, the YD, be-
tween 11 430 and 11 250 yr BP, and after 11 070 years) had
different causes because either an increase or decrease in spe-
cific compounds triggered the individual response.

We did not observe significant lag times between the re-
sponse of pollen and n-alkane data during periods of abrupt
change (i.e., on multidecadal timescales), indicating n-alkane
residence times in the catchment below our sampling res-
duction (decades). However, organic geochemical data in-
tegrated different information compared to pollen, as there
is evidence that Pinus sylvestris, despite being a dominant
tree species in the TRZ catchment, has a minor impact on
n-alkane-based parameters. Overall, this study shows that
ACL and ratios of n-alkanes are suitable integrative proxies
to track major and abrupt vegetation changes in a local set-
ing, for example in lacustrine environments with relatively
small catchments.

Data availability. Data can be accessed in Tables S1 and S2 in the
Supplement.

Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/cp-14-1607-2018-supplement.

Author contributions. FO and AB provided the samples and the
age–depth model. BA processed and analyzed the samples in the lab
of DS. MS and AMN provided pollen data and unpublished macro-
fossil data. DS acquired financial support and conceived the project.
BA wrote the paper with contributions from all coauthors.

Competing interests. The authors declare that they have no con-

Conflict of interest. The authors declare that they have no con-
