Abstract. The early Paleogene is marked by multiple negative carbon isotope excursions (CIEs) that reflect massive short-term carbon cycle perturbations that coincide with significant warming during a high-pCO2 world, affecting both marine and terrestrial ecosystems. Records of such hyperthermals from the marine–terrestrial interface (e.g., estuarine swamps and mire deposits) are therefore of great interest as their present-day counterparts are highly vulnerable to future climate and sea level change. Here, we assess palaeoenvironmental changes of midlatitudinal late Paleocene–early Eocene peat mire records along the paleo-North Sea coast. We provide carbon isotope data of bulk organic matter (δ13C TOC), organic carbon content (%TOC), and palynological data from an extensive peat mire deposited at a midlatitudinal (ca. 41° N) coastal site (Schöningen, Germany). The δ13C TOC data show a carbon isotope excursion of −1.3‰ (mean decrease in δ13C TOC; −1.7‰ at the onset of CIE) coeval with a conspicuous Apectodinium acme. Due to the exceptionally large stratigraphic thickness of the CIE at Schöningen (10 m of section) we established a detailed palynological record that indicates only minor changes in paleovegetation leading into and during this event. Instead, paleovegetation changes mostly follow natural successions in response to changes along the marine–terrestrial interface. The available age constraints for the Schöningen Formation hamper a solid assignment of the detected CIE to a particular hyperthermal such as the Paleocene–Eocene Thermal Maximum (PETM) or any succeeding hyperthermal event such as the Eocene Thermal Maximum 2 (ETM2).

Compared to other nearby peat mire records (Cobham, UK; Vasterival, F) it appears that wetland deposits around the Paleogene North Sea have a consistent CIE magnitude of ca. −1.3‰ in δ13C TOC. Moreover, the Schöningen record shares major characteristics with the Cobham Lignite PETM record, including evidence for increased fire activity prior to the CIE, minor plant species change during the hyperthermal, a reduced CIE in δ13C TOC, and drowning of the mire (marine ingressions) during much of the Schöningen CIE event. This suggests that either the Schöningen CIE reflects the PETM or that early Paleogene hyperthermals similarly affected palaeoenvironmental conditions of a major segment of the paleo-North Sea coast.

1 Introduction

Early Cenozoic short-term hyperthermals, such as the Paleocene–Eocene Thermal Maximum (PETM) and the Eocene Thermal Maximum 2 (ETM2), reflect rapid global warming events that punctuate the already warm Palaeogene climate. These events coincide with perturbations in the global carbon cycle, manifested in negative carbon isotope excursions (CIE) due to a rapid and massive 13C-depleted carbon input into the ocean–atmosphere system. CIEs are a recurrent phenomenon of early and middle Eocene climate dynamics (e.g., Kennett and Scott, 1991; Cramer et al., 2003; Lourens et al., 2005; Zachos et al., 2003, 2008, 2010; Sluijs and Dickens, 2012).
Among the early Cenozoic climate perturbations, the Paleocene–Eocene Thermal Maximum (PETM) at ∼56 Ma is one of the best-investigated Cenozoic hyperthermals with local warming of up to 10 °C (e.g., Dunkley Jones et al., 2013; Frieling et al., 2014; Sluïjs et al., 2006, 2011; Zachos et al., 2003). In general, the PETM-related CIE consists of a rapid onset, the main body of the excursion, and a recovery composed of an early rapid phase followed by a more gradual increase in δ13C values (McInerney and Wing, 2011). Despite this general pattern, the magnitude of the CIE varies largely between different environmental settings (on average −2.5 ‰ to −5.5 ‰) and within individual records (−0.6 ‰ to −8.0 ‰) (see compilation of McInerney and Wing, 2011). The CIE is typically larger in continental than in marine depositional environments. Subsequent to the PETM, the ETM2 at ∼54 Ma represents the next prominent hyperthermal similarly associated with rapid 13C-depleted carbon input to the ocean–atmosphere system, resulting in a marine CIE of ∼−1.5 ‰ and global warming by several degrees (∼3–5 °C) (Cramer et al., 2003; Lourens et al., 2005; Sluïjs et al., 2009; Stap et al., 2010; Frieling et al., 2014).

Multiple hypotheses exist to explain the 13C-depleted carbon input to the atmosphere–ocean system during the early Cenozoic, including methane clathrate destabilization on continental slopes (DICKENS et al., 1995), thermogenic methane formation by magma injections into organic-rich mudstones (Svensen et al., 2004), oxidation of vast amounts of organic matter by drying of epicontinental seas (Higgins and Schrag, 2006), orbitally triggered permafrost thawing (DeConto et al., 2012), and wildfires and burning of peatlands (Kurtz et al., 2003) due to natural causes or triggered by a meteorite impact (Cramer and Kent, 2005; Kent et al., 2003). The magnitude of CIEs, taking into account (1) variable preservation of the CIEs in terms of magnitude and duration in different archives (TRAMPUSH and Hajek, 2017; Lyons et al., 2019) and (2) carbon source effects resulting in local variations of CIEs (Sluïjs and Dickens, 2012), potentially reveals the source of carbon input to the ocean–atmosphere system. The mixing of terrestrial and marine organic carbon, in particular, exerts a strong effect on the preserved CIE and calls for careful disentangling of the carbon isotope signal between these two components (Sluïjs and Dickens, 2012).

Thus, assessing the duration and magnitude of CIEs related to global carbon cycle perturbations at the marine–terrestrial interface is of great interest, as near-coastal ecosystems are especially vulnerable to global climate change and sea level rise causing large ecological and economic threats (IPCC, 2014). Near-coastal wetlands play a major role in the global carbon cycle by storing large quantities of terrestrial organic carbon (e.g., RAGHOEBARISING et al., 2005; Rumpel et al., 2018) but are simultaneously a primary source of methane emissions to the atmosphere (CHRISTENSEN et al., 2003; Kirschke et al., 2013). Peatland conservation has thus become one of the pressing tasks to meet the Paris Agreement (Rumpel et al., 2018), as under global warming peatlands are likely to contribute significantly to future CO2 emissions (e.g., DORREPAAL et al., 2009; Rumpel et al., 2018) and likely did so during the PETM (PANCOST et al., 2007). Extensive wetlands with peat-forming mires and swamps were widespread in the European realm during the Cenozoic and may have significantly contributed to Cenozoic climate evolution on a global scale (e.g., KURTZ et al., 2003; PANCOST et al., 2007).

Here, we explore carbon isotope ratios of bulk organic matter (δ13C) and the total organic matter content (%TOC) from the lower part of the Paleocene–Eocene Schöneningen Formation (Germany). We evaluate the corresponding palynological record to assess the paleoenvironmental evolution of this wetland and compare our results to associated Paleogene lignite records along the paleo-North Sea (Cobham, UK; Vasterival, F) to identify potential regionally coherent paleoenvironmental patterns.

2 Study site and age constraints of the Schöneningen Formation

The Schöneningen opencast mine (northern Germany) is the type locality of the Schöneningen Formation (RIEGEL et al., 2012) and offers the opportunity to study Paleocene–Eocene climate change in wetland deposits along the paleo-North Sea coast (Fig. 1a) (RIEGEL et al., 2012). The Schöneningen Formation is mainly early Eocene in age but probably includes the topmost part of the Paleocene. It comprises ∼150 m of alternating lignite seams and clastic interbeds (Fig. 1b) (BRANDES et al., 2012; Osman et al., 2013; Riegel et al., 2012). Detailed age constraints of the Schöneningen Formation are weak and restricted to dinocyst assemblages and scattered radiometric ages from a core at Emmersstedt ca. 20 km north of Schöneningen that were tentatively correlated with the Schöneningen lignite succession (RIEGEL et al., 2012). It has been speculated that the lower part of the Schöneningen Formation covers the PETM, as the shallow marine deposits of Interbed 2 exhibit a conspicuous peak in the abundance of dinoflagellate cysts of the genus Apectodinium (RIEGEL et al., 2012). The occurrence of high abundances of the species Apectodinium augustum in midlatitudinal to high-latitude sediments (SCHÖNINGEN paleolatitude is ∼41° N; van HINSBERGEN et al., 2015; see also Supplement Table S1) has been proven to be indicative of the PETM (BUJAK and BRINKHUIS, 1998; CROUCH et al., 2001; HEILMANN-CLAUSEN et al., 1985; IAKOVLEVA et al., 2001; SLUÏJS and BRINKHUIS, 2009; SLUÏJS et al., 2006, 2007). The dinoflagellate cysts of the marine-influenced Interbeds 1 and 2 only allow for an assignment of these deposits to dinocyst zone D5, which is characterized by the mass occurrence of Apectodinium spp. and includes the Paleocene–Eocene boundary (AHRENDT et al., 1995; KÖTHE, 2003). A further distinction in subzones D5na (uppermost Paleocene) and D5nb (lowermost Eocene) is based on the last occurrence of Apectodinium augustum (KÖTHE, 2003).
3 Material and methods

3.1 Studied sections and sampling

Active lignite mining (1978–2016) yielded excellent exposures in the now-abandoned opencast mines at Schöningen (Fig. 1a, Sect. S1, and Fig. S1 in the Supplement). This allowed for dense sampling of the Paleocene–Eocene Schöningen Formation (Fig. 1b) in the western rim syncline of the NW–SE-trending Helmstedt–Staßfurt salt wall. From the >4000 samples, collected from more than 50 individual sections over ~30 years accompanying the mining activities in Schöningen–Südfeld, we selected 121 samples for isotopic analyses. These samples comprise two of the lower lignite seams (Seam 1 and Seam 2) and the corresponding clastic interbed, presumably covering the latest Paleocene and early Eocene. The ca. 16 m record consists of three individual sections recovered laterally within 50 m. Stratigraphic continuation could be ensured by the well-exposed, undisturbed, and laterally traceable lignite seams (e.g., Riegel et al., 2012). The transitions between the seams and the marine interbeds are rather abrupt (see Sect. S1 and Fig. S1); however, there is no evidence for any major hiatus. In order to get a more comprehensive picture of environmental and vegetation change in the latest Paleocene–early Eocene, samples from the underlying sediments (Main Seam and Interbed 1) are included in our palynological analyses.

The lower three seams (Main Seam, Seams 1 and 2; Fig. 1b) resemble each other in their petrographic and palynological characteristics. In general, the lignite seams are composed of an alternation of dark and medium brown lay-
ers, which often have tree stumps at their base and layers or lenses of charcoal with tissue preservation in the coal matrix (Riegel et al., 2012; Robson et al., 2015). Silts to medium-grained sands dominate the clastic interbeds. There is still debate about the prevailing deposition conditions of the clastic interbeds (Osman et al., 2013; Riegel et al., 2012). Interbed 1 includes Apectodinium spp., mostly in low numbers, and shows little evidence for fully marine conditions but rather indicates local emergence (occurrence of driftwood and occasional rooting). In contrast, Interbed 2, containing rich dinocyst assemblages with peak abundances of Apectodinium homomorphum and other Apectodinium species (Fig. S4), is indicative of shallow marine depositional conditions (Riegel et al., 2012). For a more detailed description of the lithology of the sampled sections, the reader is referred to Riegel and Wilde (2016) and Riegel et al. (2012) as well as to the detailed logs in the Supplement (Sect. S1, Fig. S1).

3.2 Carbon isotope analyses

A total of 121 samples were selected for analysis of total organic carbon content (%TOC) and carbon isotope composition of bulk organic matter ($\delta^{13}$C$_{TOC}$), providing a %TOC and $\delta^{13}$C$_{TOC}$ record of 16 m with an average sample spacing of $\sim$ 13 cm. Sample preparation included freeze-drying, grinding, removal of inorganic carbon (using 10 % HCl for 24 h at 40 °C), centrifugation (four times at 2800 to 3000 rpm for 4 to 8 min), and sample drying (24 h at 40 °C). About $\sim$ 0.2 mg (lignite samples) and up to $\sim$ 6 mg (marine interbed samples) were analyzed using a Flash EA 1112 (Thermo Finnigan) coupled to a MAT 253 gas source mass spectrometer (Thermo Finnigan) at the Goethe University–Senckenberg BiK-F Joint Stable Isotope Facility (Frankfurt). USGS 24 and IAEA-CH-7 standard materials were analyzed on a daily basis, and replicate measurements of reference materials and samples indicate an uncertainty of $<$0.2 % for measured $\delta^{13}$C$_{TOC}$ values. Total organic carbon concentrations (%) were calculated by relating the signal size of the samples and the averaged signal size of the daily standards (USGS 24, n = 8). The typical error is $\sim$ 0.5 % based on mass spectrometric analysis and the maximum difference in TOC contents of replicate measurements (including weighing uncertainties) was $\sim$ 7 %.

3.3 Palynological analyses

The palynological analysis is primarily based on revised data of 59 samples from a section between the top of the Main Seam and the top of Seam 2 (Hamer-Schiemann, 1998). For palynological processing, lignite samples were crushed to a particle size of 1 to 2 mm. All lignite and interbed samples were carefully treated with hot 15 % hydrogen peroxide (H$_2$O$_2$) and ca. 5 % potassium hydroxide (KOH) for 1 to 2 h. In our experience this does not alter the palynomorph record to a major extent. The clastic samples were further treated with 30 % hydrofluoric acid (HF) for several days. HF was removed by five to six steps of decanting and diluting. All samples were sieved through a 10 µm mesh sieve. Residues are stored in glycercine, and permanent glycerine jelly slides were made. To obtain a representative dataset, at least 300 individual grains of pollen and spores were counted per sample at $\times$400 magnification (data in Table S3). The palynomorphs were mainly identified based on the systematic–taxonomic studies of Thomson and Pflug (1953), Krutzsch (1970), Thiele-Pfeiffer (1988), Nickel (1996), Hammer-Schiemann (1998), and Lenz (2005). The simplified pollen diagram shows the abundance of the most important palynomorphs in percentages. Pollen and spores were calculated to 100 %, whereas dinoflagellate cysts (Apectodinium spp.) and other algae were added as additional percentages (in percent of the total pollen sum).

To reveal compositional differences between the different coal seams and interbeds, nonmetric multidimensional scaling (NMDS; Shepard, 1962a, b; Kruskal, 1964) was performed for the pollen and spore dataset excluding algae. NMDS is the most robust unconstrained ordination method in ecology (Minchin, 1987) and has been successfully applied to palynological data in previous studies (e.g., Oswald et al., 2007; Jardine and Harrington, 2008; Mander et al., 2010; Ghilardi and O’Connell, 2013; Broothaerts et al., 2014; Lenz and Wilde, 2018). The method avoids the assumption of a linear response model or a unimodal response model between the palynomorph taxa and the underlying environmental gradients and avoids the requirement of normality of data. For NDMS the Bray–Curtis dissimilarity and the Wisconsin double standardized raw data values have been used (Bray and Curtis, 1957; Gauch and Scruggs, 1979; Oksanen, 2007). Wisconsin standardization scales the abundance of each taxon to its maximum value and represents the abundance of each taxon by its proportion in the sample (Mander et al., 2010). This equalizes the effects of rare and abundant taxa and removes the influence of sample size on the analysis (Von Tongeren, 1995; Jardine and Harrington, 2008).

4 Results and discussion

4.1 The CIE in the basal Schöningen Formation

The total organic carbon content across the analyzed section ranges from $\sim$ 0.2 % to 69 % and correlates with lithology, with TOC contents generally $>$50 % in the lignite seams and $<$10 % in the clastic interbed (Fig. 2a). Carbon isotope ratios of bulk organic matter range from $-25.1$ ‰ to $-28.3$ ‰ (Fig. 2b). In the basal part (0 to 2.9 m) of the section $\delta^{13}$C$_{TOC}$ varies between $-25.7$ ‰ and $-27.4$ ‰ (average $\delta^{13}$C$_{TOC} = -26.76 \pm 0.46$ ‰, n = 26). At 3.0 m of section, $\delta^{13}$C$_{TOC}$ abruptly decreases to values as low as $-28.3$ ‰ and remains low within the next 0.7 m (average $\delta^{13}$C$_{TOC} = -28.02$ ‰...
0.19‰, n = 8). At 3.9 m of section, δ¹³C_TOC values increase to 26.95 ± 0.16‰ (n = 37) and remain constant (−26.5‰ to −27.3‰) for the next 6.5 m before they decrease again to −28.1‰ (at 10.6 m) and reach values as low as −28.3‰ (at 12.4 m). Between 12.4 and 12.9 m δ¹³C_TOC increases to a value of −26.2‰ (at 12.9 m) and attains an average of δ¹³C_TOC = −26.20 ± 0.43‰ (n = 18, 12.9 to 15.8 m), very similar to the pre-excursion δ¹³C_TOC values in the 0−2.9 m part of the section.

Overall, the δ¹³C_TOC data show four conspicuous shifts across the record (Fig. 2b): the basal shift at 3.0 m of section to lower δ¹³C_TOC values (Δδ¹³C_TOC, single samples at −3 m = −1.7‰) and the uppermost gradual increase between 12.4 and 12.9 m back to higher δ¹³C_TOC values (Δδ¹³C_TOC, 12.4−12.9 m = +2.1‰) occur within individual lignite seams. Thus, these two shifts are independent of major lithological changes (Fig. 2). In contrast, the δ¹³C_TOC shifts at 3.9 m (Δδ¹³C_TOC, 3.9 m = +0.9) and between 10.3 and 10.6 m (Δδ¹³C_TOC, 10.6 m = −1.3‰) correlate with lithological changes. Most importantly, the remarkably stable δ¹³C_TOC values in the central part of the section (3.9 to 10.6 m) are restricted to the clastic Interbed 2 deposited under marine conditions. Omitting these marine samples (with %TOC < 10‰) indicates that the low δ¹³C_TOC values smoothly tie between Seam 1 and Seam 2 with an average value of −27.68 ± 0.43‰, whereas δ¹³C_TOC values in the shallow marine sediments (Interbed 2) are ∼0.7‰ higher. Higher δ¹³C_TOC values in the clastic interbed may be surprising at first as marine organic matter is generally more depleted in δ¹³C compared to terrestrial organic matter (e.g., Sluijs and Dickens, 2012). However, given the near-coastal setting of the Schöningen locality during the early Paleogene we can expect a significant terrestrial contribution to the TOC content (confirmed by the presence of abundant terrestrially derived pollen; Fig. 5), which would increase the δ¹³C_TOC values (Sluijs and Dickens, 2012). Interestingly, the average δ¹³C_TOC value (−27.68 ± 0.43‰) agrees well with CIE-related δ¹³C_TOC values with high (∼80 ‰) terrestrial contributions of organic matter (data from IODP site 4A; Sluijs and Dickens, 2012). The low δ¹³C_TOC values at the base of Interbed 2 (three samples with ∼−28‰) may indicate reworking of the underlying peat deposits, which is supported by scattered lignite material in the sediments.

Detailed biogeochemical investigations of Seam 1 in a nearby section from Schöningen also showed a gradual depletion in δ¹³C_TOC as well as in mid- and long-chain n-alkanes at the top of Seam 1 (Inglis et al., 2015, 2017). Moreover, the absolute %TOC and δ¹³C_TOC values (Inglis et al., 2015) are in very good agreement with our newly derived data and reveal a statistically significant (single-tailed t test p < 0.000003) negative shift in δ¹³C_TOC values at the top of Seam 1 with Δδ¹³C_TOC = −1.0‰ (from average δ¹³C_TOC = −26.53 ± 0.30‰ to δ¹³C_TOC = −27.52 ± 0.09‰) (Fig. 3a).

We consider the excursion in δ¹³C_TOC within the lignite seams, which is thus independent of lithological changes, to demark the onset and termination of a CIE in the basal part of the Schöningen Formation. It shows an abrupt decrease (Δδ¹³C_TOC = −1.7‰ within 0.08 m of section; 2.94 to 3.02 m) but a more gradual increase in δ¹³C_TOC values (Δδ¹³C_TOC = +2.1‰ within 0.52 m of section; 12.41 to 12.93 m). The major shift in δ¹³C_TOC occurs entirely within the lignite seam with uniform %TOC, virtually unaffected by marine influences at this stratigraphic level as indicated by rather abrupt lithological transitions on a centimeter–decimeter scale (see Sect. SI1) and defined palynological transitions between the terrestrial peat deposits to the marine interbed (see Sect. 4.3). Thus, we exclude potential mixing of terrestrial and marine (with generally lower δ¹³C values) organic matter to be the main driver for the detected carbon isotope excursion.

The described CIE occurs in the two seams surrounding the clastic interbed that includes a prominent Apectodinium acme (Riegel et al., 2012). This indicates significant differences in paleoenvironmental conditions when compared to the majority of marine interbeds of the Schöningen Formation that lack abundant Apectodinium spp. Thus, the detected CIE is very likely associated with carbon cycle perturbation during an early Paleogene hyperthermal. At present, however, we cannot unequivocally assign the Schöningen CIE to the PETM or the ETM2.
Figure 3. Comparison of midlatitudinal wetland δ\(^{13}\)C\(_{\text{TOC}}\) records surrounding the paleo-North Sea (see Fig. 1): (a) carbon isotopic differences at the onset of the CIE, (b) Vasterival, France (Storme et al., 2012), (c) Cobham, UK (Collinson et al., 2003), (d) Schöningen, Germany (this study: green symbols; Inglis et al., 2015: grey symbols). Note the different stratigraphic thicknesses due to different sediment accumulation and preservation conditions in the individual depositional environments.

4.2 The magnitude of the CIE in European lignite records

Even though the magnitudes of the CIE vary widely among proxy records across the PETM and to a lesser extent across the ETM2 event (see McInerney and Wing, 2011; Sluijs and Dickens, 2012), the Schöningen CIE is small given the generally large CIE in bulk organic carbon in terrestrial settings (McInerney and Wing, 2011). Terrestrial CIEs related to the PETM are commonly enhanced by \(\sim 1\%_\circ\) to \(3\%_\circ\) compared to those inferred from marine organic matter (typically in the range of \(-2\%_\circ\) to \(-3\%_\circ\); e.g., Cramer and Kent, 2005; McInerney and Wing, 2011; Sluijs and Dickens, 2012) and the same may apply for the terrestrial expression of the ETM2. Thus, it may be questioned whether the reduced magnitude of the CIE at Schöningen is unique due to (1) local conditions and can actually be related to the PETM, (2) represents another early Eocene hyperthermal, or (3) is an independent feature of midlatitudinal European near-coastal environments.

In order to address this question, we compare our δ\(^{13}\)C\(_{\text{TOC}}\) record and the adjacent Schöningen record of Inglis et al. (2015) with published peat mire records along the paleo-North Sea coastline (Fig. 1), namely the Cobham Lignite (UK) (Collinson et al., 2003, 2009; Pancost et al., 2007) and the Vasterival section (France) (Garel et al., 2013; Storme et al., 2012) that were both assigned to the PETM. Interestingly, all three lignite deposits share characteristic features (Table 1; Figs. 3 and 4).

1. Absolute δ\(^{13}\)C\(_{\text{TOC}}\) values and the range in δ\(^{13}\)C\(_{\text{TOC}}\) values (\(\sim 3.2\%_\circ\)) are very similar (Fig. 3 and Table 1).
2. All three records attain similar minimum δ\(^{13}\)C\(_{\text{TOC}}\) values during the CIE (\(-27.5\%_\circ\) to \(-28.8\%_\circ\)), averaging 28.05 ± 0.5\%_\circ\) (Fig. 4).
3. At the onset of the CIE the magnitude of changes in δ\(^{13}\)C\(_{\text{TOC}}\) (calculated as the difference between the last pre-CIE value and the first CIE value) ranges only between \(-1.4\%_\circ\) and \(-1.8\%_\circ\) (Fig. 3).
4. Magnitudes of the CIE in bulk organic matter calculated as the difference between the mean pre-CIE and the mean CIE values range from \(-0.9\%_\circ\) to \(-1.6\%_\circ\). CIEs calculated as the difference between the mean pre-CIE values and the most negative value during the CIE (following McInerney and Wing, 2011; see Fig. 4) yield magnitudes of \(-1.1\%_\circ\) to \(-2.3\%_\circ\) (Table 1).

Even though suggestive, these similarities do not provide unequivocal evidence that the Schöningen CIE reflects the
to purely continental terrestrial archives but yield a very consistent behavior of these wetlands during latest Paleocene–Eocene thermal events. Overall, the comparison of these geographically adjacent deposits shows that all reported CIE magnitudes of lignite records are striking and may argue for a quite uniform behavior of these wetlands during latest Paleocene–Eocene thermal events.

Overall, the comparison of these geographically adjacent deposits shows that all reported CIE magnitudes of lignite records are striking and may argue for a quite uniform behavior of these wetlands during latest Paleocene–Eocene thermal events.

PETM; it may well represent another early Eocene CIE. However, the similarity of the CIEs (two of them assigned to the PETM; Collinson et al., 2003, 2009; Pancost et al., 2007; Garel et al., 2013; Storme et al., 2012) between these adjacent lignite records is striking and may argue for a quite uniform behavior of these wetlands during latest Paleocene–early Eocene thermal events.

Figure 4. Comparison of terrestrial carbon isotope excursions (CIE). Data from plant-derived lipids (yellow) and soil organic matter (green) are from McInerney and Wing (2011). Data from peat-derived bulk organic matter are compiled from new (this study) and published studies (Collinson et al., 2003; Inglis et al., 2015; Storme et al., 2012). Whereas the pre- and post-CIE values represent mean δ13C values, the CIE is given as the most negative values, following McInerney and Wing (2011).

PETM; it may well represent another early Eocene CIE. However, the similarity of the CIEs (two of them assigned to the PETM; Collinson et al., 2003, 2009; Pancost et al., 2007; Garel et al., 2013; Storme et al., 2012) between these adjacent lignite records is striking and may argue for a quite uniform behavior of these wetlands during latest Paleocene–early Eocene thermal events.

Overall, the comparison of these geographically adjacent deposits shows that all reported CIE magnitudes of lignite records are striking and may argue for a quite uniform behavior of these wetlands during latest Paleocene–Eocene thermal events.

Overall, the comparison of these geographically adjacent deposits shows that all reported CIE magnitudes of lignite records are striking and may argue for a quite uniform behavior of these wetlands during latest Paleocene–Eocene thermal events.
ment, the preservation states, or the plant communities but at the same time excluded those mechanisms because the major shift in the carbon isotope values occurred without any major lithological or floral changes. These findings are similar to our observations for the Schöningen lignites.

Moreover, marine sediments from the paleo-North Sea exhibit an enhanced CIE of 6‰–8‰ e that has been explained by increased terrigenous input (Heilmann-Clausen and Schmitz, 2000; Schmitz et al., 2004; Sluijs and Dickens, 2002). Land-plant-derived δ13C values of n-alkanes from two sections of the paleo-North Sea (Denmark) record a decrease of 4‰–7‰ e (Schoon et al., 2015), clearly showing that the PETM affected the biosphere around the paleo-North Sea in terms of recording the CIE. However, Schoon et al. (2015) also noted that the differences in the CIE likely arose from local differences in the plant communities or precipitation patterns. Taken together, we think that a local change in vegetation, altering the carbon isotope “input signal” to the peat mires, is unlikely to account for the reduced CIE in the Schöningen lignites.

An alternative scenario is differential degradation and/or preservation of organic matter in the Schöningen peat mires during a hyperthermal event. Carbon isotope discrimination between litter input and stored (soil) organic matter during degradation or decomposition is governed by fractionation processes during metabolism (typically enriching the residual carbon stock in 13C) and the selective utilization of compounds (with differing δ13C values) (e.g., Santruckova et al., 2000). The latter process apparently dominates and can either enhance or suppress a metabolism-related fractionation signal (Santruckova et al., 2000). Minor warming of ~1°C can cause significant increases in carbon respiration rates in modern high-latitude peatlands (on average by 52% in spring to 60% in summer; Dorrepaal et al., 2009). Contemporaneous to the increased respiration rates, an increase in the carbon isotope ratios of the respired CO2 has been interpreted as a shift towards respiration of less 13C-depleted carbon stocks, likely due to a change in microbial communities.

Even though the paleoenvironmental setting of the Paleogene peat mire clearly differs from the modern high-latitude mires (Dorrepaal et al., 2009), it seems likely that warming related to a hyperthermal generally affected peat mires by increasing respiration rates and causing changes in the microbial community. This could have resulted in specific changes in the δ13C values of the respired and residual carbon stocks in peatlands. Indeed, Pancost et al. (2007) attributed the shift in δ13C values of hopanes, a biomarker derived from bacteria, in the Cobham Lignite to an increase in the population of methanotrophic bacteria and, possibly, decreased heterotrophic biomass in this peatland during the PETM. Thus, this study documents a major shift in the microbial community across the PETM (Pancost et al., 2007). Hopane data from Schöningen have been interpreted in terms of a generally mixed methanotrophic and heterotrophic bacterial population (Inglis et al., 2015). The decreasing trend in δ13C values of hopanes at the top of Seam 1, coinciding with the position of our detected CIE, may indicate slight changes in the bacterial communities associated with the inferred hyperthermal, even though no significant warming trend based on branched glycerol dialkyl glycerol tetraethers (brGDGTs) was detected here (Inglis et al., 2015, 2017). Higher-than-expected δ13C TOC values during the CIE relative to pre-CIE values could result from enhanced microbial degradation processes and changed microbial communities that decompose more 13C-depleted recalcitrant matter. Generally enhanced respiration rates and changes in the microbial communities due to warming (and wetting) are also likely to appear on a regional scale and are thus consistent with our finding of generally reduced CIEs in peat mires along the paleo-North Sea.

4.3 Environmental changes in the Schöningen peat mire

The repeated change from open-estuary or marine to meandering-river and peat mire environments is characteristic for the Schöningen Formation and continues even into the middle Eocene Helmstedt Formation (Fig. 1b) (Riegel et al., 2012, 2015). We extended our palynological dataset downstream to the underlying Interbed 1 and Main Seam in order to disentangle the effects of transgressions or regressions in the coastal setting, which were governed by an interplay of eustatic sea level changes, withdrawal of salt towards the salt wall, and/or changes in precipitation and subsequent runoff from the direct effects of climate perturbation during the potential hyperthermal associated with the CIE.

During the late Paleocene and early Eocene, mire forests, typical for coastal areas along the edge of the paleo-North Sea basin, existed in the area of Schöningen (e.g., Allen, 1982; Willumsen, 2004; Collinson et al., 2009). As inferred from pollen records they consisted essentially of wet swamp forests dominated by Nyssaceae and Cupressaceae s.l. and drier hardwood mire and background forests characterized by Fagaceae and Myricaceae or Betulaceae (Riegel et al., 2012, 2015). Three groups of palynomorphs can be distinguished (Fig. 5): (1) taxa that occur throughout the entire succession but with frequency maxima in the Interbeds 1 and 2 such as pollen of Cupressaceae s.l. (Inaperturopollenites spp., Cupressacidites sp.), Fagaceae or Leguminosae (Tri- colpopollenites liblarensis), Fagaceae (Tricolporopollenites cingulatum), or Myricaceae-Betulaceae (Triporopollenites robustus group); (2) taxa that are especially abundant in some of the interbed–lignite seam transitions, such as the juglandaceous pollen Plicapollis pseudoexcelsus (Main Seam–Interbed 1 and Interbed 1–Seam 1) and Thomsonipollenites magnificus (Interbed 2–Seam 2 and to a lesser extent Main Seam–Interbed 1) (the latter with unknown botanical affinity); and (3) taxa that are strictly confined to lignite seams, e.g., spores of peat mosses (Sphagnum) or spores of polypodiaceous ferns.
Figure 5. Simplified pollen diagram of the top of the Main Seam up to the top of Seam 2, showing frequency and palynological abundance changes between pre-, peak-, and post-CIE intervals. The carbon isotope data are shown for comparison. Due to the different thicknesses of the sections (see Fig. 2), it has been tied to the top and base of Seam 1 and the top and base of Seam 2. The red bar indicates the carbon isotope excursion. The palynological record is characterized by three palynological groups: (1) elements with frequency maxima in the clastic interbeds (representing the hinterland), (2) interbed–lignite seam transitional elements and back mangrove equivalents, and (3) elements dominating the lignite seams.

The separation of samples based on the dominance of one of these three palynomorph groups is reflected by the NMDS of the palynomorph data (Fig. 6a). Samples from Seams 1 and 2 plot on the left side of NMDS axis 1 in the ordination space, clearly separated from interbed samples that plot on the right side of the ordination space. This indicates the completely different palynological composition of interbed and lignite samples with the dominance of fagaceous and myricaceous or betulaceous pollen in the interbeds and of spores of peat mosses and polypodiaceous ferns in the lignites (Fig. 6a, b). Samples from the Main Seam plot in the center of the NMDS ordination space, indicating that there are slight compositional differences in comparison to Seams 1 and 2. However, the samples are only from the top of the Main Seam and may therefore not reflect the typical lignite–interbed transitions.

The fagaceous pollen *T. liblarensis* and *T. cingulum* appear to be essentially confined to the CIE (9–14 m in Fig. 5). However, when compared with the older part of the succession (0–6 m in Fig. 5), these taxa appear more frequently in the marine interbeds. Presumably, with the rise of the sea level the respective forests shifted landward and the small wind-transported fagaceous pollen became enriched in the interbeds at this site. For the same reason, pollen of the Cupressaceae s.l., indicative of a swamp forest, occur more frequently in the marine interbeds. Myricaceous- or Betulaceae-dominated forests as represented by *T. robustus*-group pollen are considered to have grown on better-drained, remote mire areas and are therefore less affected by sea level fluctuations (Riegel et al., 2012).

Floral successions at marine interbed–lignite transitions at Schöningen differ significantly from those of the middle Eocene Helmstedt Formation in nearly lacking pollen of the tropical mangrove elements *Rhizophora*, *Avicennia*, *Nypa*, and *Psilodiporites* of unknown botanical affinity (Lenz, 2005; Lenz and Riegel, 2001; Riegel et al., 2012, 2015; this study). Instead, transitions at Schöningen are characterized by *Thomsonipollis magnificus*, *Pistillipollenites mcgregorii* (Figs. 5 and 6), *Plicapollis pseudoeucelsus*, and *Pompeckjoidaepollenites subhercynicus*. The latter two are also known from the middle Eocene of the Helmstedt Formation (Lenz and Riegel, 2001). The absence of tropical mangrove elements, especially *Nypa*, has been interpreted as indicating extratropical conditions during the deposition of the Schöningen Formation in contrast to the true tropical conditions during the middle Eocene (Helmstedt Formation) (Riegel et al., 2012).

Spores of Sphagnaceae (peat mosses) and polypodiaceous ferns are typical lignite-related elements throughout much of the Schöningen Formation and often dominate the palynological assemblages (Figs. 5 and 6; Inglis et al., 2015; Riegel and Wilde, 2016; Riegel et al., 2012). The frequent and close association of these spores (*Sphagnusporites* spp., *Distantcorisporis* sp., *Tripunctisporis* sp., *Laevigatosporites* spp.) with charcoal horizons is characteristic for Seam 1 and Seam
This Sphagnum-free interval coincides with the range of the detected Schöningen CIE and could potentially reflect a response to the CIE-related climate perturbation. However, a similar distribution pattern of Sphagnum spores has been observed in the lower part of Seam 1 (Fig. 5 and Inglis et al., 2015) as well as in the Main Seam (Hammer-Schiemann, 1998), suggesting that the return of peat mosses is typical for post-fire successions of peat-forming mires following marine incursions at Schöningen. Even though Storme et al. (2012) reported dry–wet cycling across the late Paleocene and early Eocene with rather dry conditions during the main part of the CIE at Vasterival (France), we exclude overall drying as the cause of suppressed proliferation of Sphagnumae at Schöningen. Similar to the Cobham Lignite (Collinson et al., 2003), waterlogged conditions are indicated at the top of Seam 1 by the presence of freshwater phytoplankton and confirmed by multiple biomarker analyses (Inglis et al., 2015). Regional proxy records indicate increased terrestrial runoff during the warmth of the PETM (Bornemann et al., 2014; Heilmann-Clausen and Schmitz, 2000; Schmitz and Pujalte, 2003), consistent with climate model outputs that show generally increased but also more variable rainfall during the PETM (e.g., Carmichael et al., 2016, 2017). Therefore, either increased nutrient inputs to the mire and/or climatic changes during the PETM or the subsequent early Eocene hyperthermals may have restrained the proliferation of Sphagnaceae and promoted the spread of higher plants (e.g., Cupressaceae s.l. and parent plants of T. cingulum and T. liblarensis).

Compared to other Paleocene and early Eocene palynological records in the North Sea basin, which indicate significant vegetation changes due to short-lived climate perturbations such as the PETM (e.g., Beerling and Jolley, 1998; Eldrett et al., 2014), our palynological data indicate only minor changes in plant taxa associated with the detected CIE. This is confirmed by NMDS, which shows that there are no major changes in the composition of the palynomorph assemblages when comparing Seams 1 and 2 as well as Interbeds 1 and 2, as both lignite samples and interbed samples overlap in the ordination space of the NMDS (Fig. 6b). Furthermore, comparison of post-CIE with pre-CIE (Seam 1) samples as well as comparison of CIE with pre-CIE (Interbed 1) samples reveals no significant differences in the composition of the palynomorph assemblages (Fig. 6c). Therefore, long-term environmental records are needed to identify whether plant community changes were forced by (1) lithological or environmental changes, (2) (hyperthermal-related) climate changes, or (3) a combination of both. Hitherto, changes in plant communities at Schöningen seem to follow natural successions at marine–terrestrial interfaces rather than climatic patterns.

4.4 Schöningen in relation to other European lignite records

In order to place our paleoenvironmental observations in a regional framework, we compare the Schöningen record with...
the nearby lignite sites of Cobham (UK) and Vasterival (F) in which the reported CIEs have been assigned to the PETM, even though we cannot ensure (or exclude) that these records are time equivalent and represent the same hyperthermal. However, we feel that such a comparison is still valuable in order to detect similar behaviors of these Paleogene wetlands during carbon cycle perturbations.

In the Cobham Lignite record minor qualitative changes among plant species contrast with major changes in the composition of plant communities across the PETM onset, which includes the disappearance of ferns and the increase in cupressaceous conifers (Collinson et al., 2003, 2009). This is similar to Schöningen, where the disappearance of ferns prior to the onset of the CIE is followed by a similarly high but more fluctuating occurrence of Cupressaceae during the CIE. However, such a fluctuation of Cupressaceae can be seen throughout the whole record (Fig. 5).

Strikingly similar at both localities, Schöningen and Cobham, is the high abundance of charcoal prior to the detected CIEs. At Cobham, this charcoal is in close association with abundant fern spores and is most likely derived from a secondary vegetation succeeding wildfires at the onset of the PETM (Collinson et al., 2003, 2009). At Schöningen, a high abundance of charcoal occurs in Seam 1 and Seam 2 (Riegel et al., 2012; Robson et al., 2015) with particularly high charcoal contents in the upper part of Seam 1 compared to its base (Inglis et al., 2015; Robson et al., 2015). This increase in fire intensity immediately precedes the CIE. Evidence for a high frequency of wildfires from Schöningen and Cobham prior to the reported CIEs is compatible with the possibility that the Schöningen CIE could be related to the PETM and the hypothesis that peat burning was an important trigger for the CIE (Kurtz et al., 2003; Moore and Kurtz, 2008).

Another common characteristic of the lignite records at Schöningen, Cobham, and Vasterival is drowning of the peat mires just subsequent to the onset of the detected CIE (Collinson et al., 2003; Garel et al., 2013; this study; Brandes et al., 2012; Riegel et al., 2012). If the CIE in the Schöningen record is associated with the PETM, the global transgression phase (e.g., Sluijs et al., 2011) likely resulted in the deposition of marine clastic Interbed 2 at Schöningen during much of the PETM (Fig. 2). The return of the Schöningen peat mire (Seam 2) may have been caused by a decrease in the thermal expansion of the ocean and a concomitant global regression during cessation of the PETM. At the same time, increased sediment supply from the hinterland during the PETM (e.g., Bornemann et al., 2014; Heilmann-Clausen and Schmitz, 2000) filled the available accommodation space. Any subsequent Eocene hyperthermal may have resulted in a similar behavior.

5 Summary and conclusion

Bulk organic carbon isotopic and palynological data from an alternating succession of lignite and clastic deposits in the basal Schöningen Formation (Germany) show a negative CIE ($\Delta^{13}C_{TOC} = -1.7%$) and an Apectodinium acme. Our CIE record highlights the fact that the interval of highest fire frequency in the Schöningen Formation (Seam 1; Robson et al., 2015) is clearly associated with the carbon excursion. These characteristics together with the available age constraints for the formation do not allow for a robust correlation with a particular Paleocene–early Eocene hyperthermal, but they do not exclude the possibility that this CIE is related to the PETM. Paleofloral changes related to the CIE time interval are minor and most changes follow natural successions. Thus, only long-term environmental records appear suitable to distinguish if plant communities changed due to (1) lithological or environmental changes, (2) climate change associated with the CIE, or (3) a combination of both.

Tentative comparison with the $\delta^{13}C_{TOC}$ records of nearby peat mire records along the paleo-North Sea coastline (Cobham, UK; Vasterival, F) that have been associated with the PETM shows that the carbon isotopic composition of these lignites yields a reduced, compared to marine or other terrestrial archives, but consistent CIE with a magnitude of $\sim -1.3\%$, that appears to be a robust regional signal along coastal sites of the paleo-North Sea.

Common features of the Schöningen and the Cobham Lignite records emerge, such as a similar CIE, similar paleofloral successions, and drowning of peat mires during the major body of the CIE. Furthermore, both records yield evidence of increased fire activity, such as increased charcoal contents in combination with the appearance of ferns and peat mosses prior to the CIE. Overall, the similarities between these Paleogene–Eocene European wetland records are striking and it can be hypothesized that they either represent the same hyperthermal or that different Paleocene–early Eocene carbon cycle perturbations and associated hyperthermals had similar effects on midlatitudinal wetlands along the paleo-North Sea.

Data availability. All shown and discussed data are available in the Supplement.

Sample availability. Samples are stored in the Senckenberg collections and are available upon request.

Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/cp-15-1741-2019-supplement.
Author contributions. WR, VW, and AM designed the study. KM composed the paper. KM and AM conducted the geochemical analyses and evaluated the results. WR, VW, and OL provided sample material and regional geological expertise, as well as conducting palynological analyses. All authors edited the final version of this paper.

Competing interests. The authors declare that they have no conflict of interest.
