Abstract. Studying the climate of the last millennium gives the possibility to deal with a relatively well-documented climate essentially driven by natural forcings. We have performed two simulations with the IPSLCM4 climate model to evaluate the impact of Total Solar Irradiance (TSI), CO₂ and orbital forcing on secular temperature variability during the preindustrial part of the last millennium. The Northern Hemisphere (NH) temperature of the simulation reproduces the amplitude of the NH temperature reconstructions over the last millennium. Using a linear statistical decomposition we evaluated that TSI and CO₂ have similar contributions to secular temperature variability between 1425 and 1850 AD. They generate a temperature minimum comparable to the Little Ice Age shown by the temperature reconstructions. Solar forcing explains ∼80% of the NH temperature variability during the first part of the millennium (1000–1425 AD) including the Medieval Climate Anomaly (MCA). It is responsible for a warm period which occurs two centuries later than in the reconstructions. This mismatch implies that the secular variability during the MCA is not fully explained by the response of the model to the TSI reconstruction.

With a signal-noise ratio (SNR) estimate we found that the temperature signal of the forced simulation is significantly different from internal variability over area wider than ∼5.10⁶ km², i.e. approximately the extent of Europe. Orbital forcing plays a significant role in latitudes higher than 65° N in summer and supports the conclusions of a recent study on an Arctic temperature reconstruction over past two millennia. The forced variability represents at least half of the temperature signal on only ∼30% of the surface of the globe. This study suggests that regional reconstructions of the temperature between 1000 and 1850 AD are likely to show weak signatures of solar, CO₂ and orbital forcings compared to internal variability.

1 Introduction

The study of the last millennium climate has considerably increased during the last decades because it replaces the evolution of the global temperature for the last fifty years in a multi-centennial context, providing the necessary hindsight for a more comprehensive assessment of the recent climatic change. Studying this period gives the possibility to explore a relatively well-documented climate and weakly affected by anthropogenic greenhouse gases (GHGs). Before the industrial era, natural forcings such as volcanic aerosols and solar variability have likely dominated the forced variability of the Earth climate (Rind, 2002; Bauer et al., 2003; Bertrand et al., 2002; Mann et al., 1998; Robock, 2000; Hegerl et al., 2007; Crowley, 2000; Gerber et al., 2003; Jones and Mann, 2004). Several temperature reconstructions covering different areas of the globe are now available, ranging from multi-decadal to seasonal time scale. They were obtained from different proxy data such as tree rings (Briffa et al., 2004; Cook et al., 2002; Esper et al., 2002; D’Arrigo et al., 2006; Osborn et al., 2006), fossil pollen (Bjune et al., 2004; Larocque and Hall, 2004), ice cores (Jouzel et al., 2001; Vinther et al.,
2008), lake sediments (Hu et al., 2001; McKay et al., 2008), boreholes (Gonzalez-Rouco et al., 2003a), speleothems (Tan et al., 2003; Mangini et al., 2005) and historical documents (Brazdil et al., 2005). This important amount of data has been used to perform empirical reconstructions of Northern Hemisphere (NH) surface temperature over the last millennium, relying on various methods to extract the hemispheric signal (Mann et al., 2008; Ammann and Wahl, 2007; Crowley and Lowery, 2000; Moberg et al., 2005; Hegerl et al., 2007). Those reconstructions carry however important uncertainties due to the calibration method, the type of proxy used and the reconstruction algorithm (Juckes et al., 2007; Mann et al., 2008). Due to these sources of uncertainties, robust conclusions regarding temperature variability for the past 1000 years have to be drawn by confronting as much reconstructions as possible. In the Southern Hemisphere proxy data are still too sparse to produce robust hemispherical temperature reconstructions (Juckes et al., 2007; Mann et al., 2008).

This increasingly documented period displays prominent climatic features for the last millennium such as the so-called Medieval Climate Anomaly (MCA, firstly introduced by (Lamb, 1965) as the “Medieval Warm Epoch”) and the Little Ice Age (LIA hereafter; Matthes, 1939). Those two periods have emerged from historical documents relating exceptional conditions for agriculture for the former, or glaciers growing down in valleys for the latter. One main question concerning these identified periods is the extent to which they are global (or at least hemispherical) or local phenomenon (Bradley et al., 2003; Crowley and Lowery, 2000). It appears that those episodes described in Europe are not always present in all temperature reconstructions around the globe. The warmest and coldest periods of two time series can present asynchronous occurrence and differ in amplitude when comparing one region to another (Jones and Mann, 2004), although those differences can depend on the reconstruction methods (Esper and Frank, 2009). Nevertheless, at hemispherical scale the different reconstructions seem to converge toward a relatively warm period at the beginning of the last millennium, between 900 and 1300 AD, followed by a slow decrease in temperature reaching a minimum between 1600 and 1900 AD.

Climate models have been used to study the factors that could have been responsible for such climate evolution over the last millennium. Numerous modelling experiments with different levels of model complexity such as Energy Balance Models (EBM), Earth system Models of Intermediate Complexity (EMIC) and General Circulation Models (GCM) have been carried out to assess this variability (Jansen et al., 2007). Those studies show that solar variability and volcanic aerosols are the prominent drivers of the climate between 1000 and 1850 AD at hemispherical scale. (Crowley, 2000) evaluated the role of both forcings during the preindustrial era using an Energy Balance Model and showed that the low frequency variability over this period is mainly attributed to solar variability, whereas volcanic forcing is dominant on decadal to interdecadal time scales. Same conclusions were found by (Bertrand et al., 2002) with the two-dimensional sector averaged global climate model of Louvain-la-Neuve and by (Goosse and Renssen, 2004) with the ECBilt-CLIO model. But when focusing on Europe with the same set of simulations, (Goosse et al., 2006) highlighted that land use could be in a large amount responsible for the decrease in temperature between the MWP and the LIA.

Detection and attribution methods on the last millennium climate give more moderated conclusions. Volcanic eruptions are clearly discriminated by their cooling effect at a global scale, while the signature of solar variability on NH temperature reconstructions before 1850 AD is more subtle, and yields the same magnitude as the response to GHGs (Hegerl et al., 2003, 2007). Internal variability due to non-linear processes can be comparatively large especially at local scale, as shown by (Goosse et al., 2006). Using a 10,000 years EMIC with constant forcings (Hunt, 2006) found that internal processes of the model could not produce events similar to the MCA or the LIA at the hemispherical scale.

The role of the sun on climate variability during the last millennium remains unclear because of uncertainties of Total Solar Irradiance (TSI) past variations. For the period preceding the beginning of satellites measurements (1979), the TSI is typically inferred from proxy data such as measurements of cosmogenic isotopes, mainly $^{14}$C in tree rings and $^{10}$Be in ice cores (Bard et al., 2000; Muscheler et al., 2004, 2007), or observations of the Group Sunspot Number (GSN) back until 1610 (Lean et al., 1995; Krivova et al., 2007). The former is found in long archives such as ice cores or tree rings allowing to go further back in time than the GSN which displays however higher temporal resolution and is able to catch the 11-year Schwabe cycle associated to sun spots. The main TSI oscillations such as the Spörer (~1475 AD), Maunder (~1700 AD) and Dalton (~1800 AD) Minimum are relatively well dated and constrained in proxy reconstructions, but their conversion into TSI values carries important uncertainties (Bard et al., 2000). The amplitude of TSI secular variability is thus still under debate (Frohlich, 2009; Foukal et al., 2006; Frohlich and Lean, 2004). A decrease of about 0.25% of TSI during the Maunder Minimum relative to present day value produces realistic amplitude of the Northern Hemisphere temperature variability in climate models (Ammann et al., 2007). However, recent progress in solar physics (Foukal et al., 2004; Solanki and Krivova, 2006) shows that multidecadal to secular TSI variability should mainly be due to sun-spots and faculae, which implies amplitude of TSI variations between the Maunder Minimum and present day value (last thirty years mean) of around 0.1%.

In this paper we assess the impact of solar, CO$_2$ and orbital forcings on surface temperature in a state of the art coupled climate model during the preindustrial part of the last
millennium to focus on the secular variability of the temperature, from the global scale to the grid point. We analyse the temperature response in two millennium-long climate simulations achieved with the coupled model developed at the Institut Pierre-Simon Laplace (IPSL): one with constant preindustrial boundary conditions, and one driven by a TSI reconstruction, GHGs concentrations and changes in orbital parameters between 1000 and 2000 AD. The contribution of each forcings on the simulated temperature variability is evaluated with a statistical decomposition of the temperature signal allowing a quantified estimation of the forced variability from the local to the global scale.

In Sect. 2, we describe the experimental design, the climate model and the forcings used. Section 3 presents the analysis of the Northern Hemisphere surface temperature in both simulations and a comparison with temperature reconstructions, fed by an evaluation of the contribution of each forcing to the temperature variability in the forced simulation. In Sect. 4 we use a signal-to-noise ratio to compare the forced model response with the model internal variability, from the global to the local scale. This work ends in Sect. 5 with the discussion and conclusion.

2 Experimental design

We used the fully coupled climate model developed at the Institut Pierre-Simon Laplace, IPSLCM4_v2 (Marti et al., 2006). This model is composed of the LMDz4 atmosphere GCM (Hourdin et al., 2006), the OPA8.2 ocean model (Madec et al., 1998), the LIM2 sea-ice model (Fichefet and Maquedat, 1997) and ORCHIDEE 1.9.1 for continental surfaces (Krinner et al., 2005). The coupling between the different parts is done by OASIS (Valcke et al., 2000). The resolution in the atmosphere is 96×71×19, i.e. 3.75° in longitude, 2.5° in latitude, and 19 vertical levels. The ocean and sea-ice are implemented on the ORCA2 grid (averaged horizontal resolution ~2°, refined to 0.5° around the equator, 31 vertical levels). For both runs, the vegetation was set to a modern climatology from satellite observation (Myneni et al., 1997).

We ran a 110 years spin up with preindustrial GHGs concentrations and tropospheric aerosols. The last year of the spin up is the initial state for both millennium-long simulations. The first one is a 1000-year control simulation (CTRL) with the same preindustrial boundary conditions as the spin up. The surface temperature of CTRL presents a weak drift during the first 100 years (~0.11 °C/100 yrs), and remains stable during the following 900 years (10^{-3} °C/100 yrs). The total heat content of the first 300 m of the ocean increases slowly during 600 yrs (~0.9%), and then becomes stable, reflecting the longer time needed for the thermal adjustment of the ocean.

The second simulation (SGI, for Solar, Greenhouse gases and Insolation) was forced with reconstructions of Total Solar Irradiance variations, GHGs concentrations and changes in orbital parameters covering the last millennium, from 1000 to 2000 AD. We chose the TSI reconstruction provided by (Crowley, 2000) (Fig. 1a) which combines one record derived from cosmogenic nuclides flux estimates (Bard et al., 2000) and another one inferred from sunspots observations (Lean et al., 1995). The resulting amplitude of the TSI changes between the Maunder Minimum and present day values reaches 0.25% while capturing the decadal variability of sunspot cycles. The associated mean radiative forcing in Fig. 1a is estimated by dividing the TSI by four (distribution of the top of atmosphere flux on Earth surface), and multiplied by the Earth’s albedo (~0.7). We used the same reconstructions for well-mixed GHGs concentrations as those used in the fourth assessment report of the Fourth Intergovernmental Panel on Climate Change (Jansen et al., 2007) for simulations of the climate of the last millennium. Only CO₂ concentration varies significantly before 1850 AD (Frank et al., 2010; Scheffer et al., 2006). The radiative forcing associated with changes in CO₂ concentration in Fig. 1a is estimated with the equation of (Myhre et al., 1998). This equation gives a good estimate of the first order radiative forcing of CO₂ in the IPSL model (Dufresne, personal communication, 2009). Tropospheric aerosols concentrations are kept constant before 1850 AD and vary only during the industrial period following reconstructions by (Boucher and Pham, 2002). The orbital parameters were calculated annually (Laskar et al., 2004) and produce a linear decrease of insolation at high latitudes in summer. The associated radiative forcing is null when averaged at annual and global scale (only influenced by changes in eccentricity, negligible during the last millennium), but can be important when considering high latitudes and seasonal means (Fig. 1b). Finally, we estimated the very low frequency trend in the CTRL with a cubic spline function (Green and Silverman, 1994) and removed it from SGI and CTRL for the following analyses.

3 Northern Hemisphere temperature

3.1 General behavior

The first step of this study is to evaluate the skill of the experimental setup at reproducing the major secular temperature evolution described by the temperature reconstructions. Figure 1c shows the Northern Hemisphere (NH) temperature of the simulations SGI and CTRL plotted over the reconstructions overlap provided by Osborn and Briffa for the IPCC AR4 (Jansen et al., 2007). This overlap represents the confidence interval associated to the ten NH temperature reconstructions available at this time. Also shown are the upper and lower boundaries of a set of numerical simulations from the IPCC AR4 (Mann et al., 2005; Gonzalez-Rouco et al., 2003b; Jansen et al., 2007; Gonzalez-Rouco et al., 2006; Goosse et al., 2005) and from (Swingedouw et al., 2010)
Figure 1. (a) Radiative forcing on the Northern Hemisphere of the Total Solar Irradiance (TSI) reconstruction from Crowley (2000) (black line), CO$_2$ (blue line) and orbital forcing (dashed line). The total anthropogenic forcing (orange line) is the radiative forcing of all the well-mixed greenhouse gases estimated by (Dufresne et al., 2005) and the radiative forcing of the tropospheric aerosols reconstructed by (Boucher and Pham, 2002), minus the radiative forcing of the CO$_2$ (blue line). On the right are represented the axis giving the values of TSI at the top of the atmosphere and CO$_2$ concentrations implemented in the model. The anomalies are calculated relative to the 1500–1899 AD reference period. (b) Radiative forcing of the downward short wave flux at the top of the atmosphere in the model at 65°N (grey line) modulated by both TSI variations and orbital parameters (Laskar et al., 2004) and changes in insolation alone (black line). The values are represented on anomalies relative to the 1000–2000 AD period. (c) Northern Hemisphere temperature anomalies relative to the 1500–1899 AD reference period. The thick red line represents the SGI simulation forced by TSI, GHGs, anthropogenic aerosols and orbital forcing described in panel (a), and the dashed red line shows the complementary run VHIST on the industrial period with the volcanic forcing (not shown) used in the ENSEMBLE project (Royer et al., 2009). The shaded area corresponds to the reconstructions overlap performed by Osborn and Briffa (Jansen et al., 2007). The thin black lines depict the upper and lower boundaries of a set of numerical simulations taken from the IPCC AR4 and (Swingedouw et al., 2010), achieved with similar solar and GHGs forcing. The thin green line shows the NH temperature of the preindustrial control run (CTRL), and the thick dark green line shows the low frequency NH temperature trend estimated with a cubic spline function in CTRL. This trend has been removed from the SGI and CTRL NH temperature time series represented in this figure. All the series have been smoothed with a 10-yr running mean.

Figure 2. Comparisons between the recent reconstructions of the Northern Hemisphere surface temperature with SGI (red lines), on the 1000–1850 AD period. The upper panel (a) shows the reconstruction provided by (Mann et al., 2008) (blue lines), using both land and ocean data with the EIV method. On panel (b) the green lines correspond to the reconstruction of (Moberg et al., 2005), and the lower panel (c) shows the reconstruction of (Ammann and Wahl, 2007) (blue grey lines). The thin lines are the 10yr-running mean time series, sampled every ten years, and the thick lines are the cubic spline equivalent in number of degrees of freedom to a 50yr running mean. The anomalies are calculated relative to the 1000–1850 period.

(SW2010 hereafter) chosen here because they used similar solar and GHGs forcings as used in the present study. They also take into account volcanic forcing during the last millennium, with a TSI damping to represent the direct radiative impact of the volcanoes in IPCC AR4 simulations, or with a reconstruction of the optical thickness of the volcanic aerosols in SW2010. This allows a comparison of the NH temperature secular variability between SGI and similar numerical exercises available using a volcanic forcing.

The SGI simulation lies within the interval of the NH temperature reconstructions (Fig. 1c). It shows secular temperature variability very close to the IPCC and SW2010 simulations, apart from the pronounced cooling decadal events due to the volcanoes, especially around 1200, 1450 and 1815 AD. The main secular patterns of the NH temperature of SGI are a two-century warm period around 1200 AD, followed by a temperature decrease leading to the coldest period around 1700 AD. Those warm and cold periods in SGI are identified
as analogues of the MCA for the warm period and the LIA for the cold period.

For a quantitative evaluation of the NH temperature variability in SGI we compared our simulation with three recent Northern Hemisphere temperature reconstructions (Fig. 2), provided by (Amman and Wahl, 2007) (AW07 hereafter), (Moberg et al., 2005) (Mob05 hereafter) and the temperature reconstruction obtained with the Error In Variables reconstruction method, calibrated on land and ocean data by (Mann et al., 2008) (M08 hereafter). The reconstructions show different amplitudes of temperature secular evolution, and reflect the important uncertainties linked to the proxy and the reconstruction method used. We can infer consistent information from those datasets only when a common pattern is identified. We smoothed both SGI NH temperature and temperature reconstructions time series with a 10-year running mean and sampled every 10 years to respect the number of degrees of freedom. We also computed an estimate of the lower frequency evolution with a cubic spline function (Green and Silverman, 1994) with seventeen degrees of freedom, corresponding to a ~50-year running mean.

The variance of the ten-year smoothed SGI time series between 1000 and 1850 AD is 0.037 °C². It lies between the variance of Mob05 (0.05 °C²) and M08 (0.024 °C²) and supports the realistic amplitude of the variability in the SGI simulation. The correlation coefficients with Mob05 and M08 are 0.59 and 0.4 (p-value<10⁻⁵) respectively, and 0.18 with AW07 (p-value<0.09). The correlation coefficients between the reconstructions range from 0.67 to 0.8 (p-value<2.10⁻¹⁶). The SGI simulation shows less agreement with the temperature reconstructions than the reconstructions between them.

The weather maximum occurs around 1200 AD in SGI, whereas it appears around 1000 AD in the reconstructions overlap. The amplitude of the temperature variability in AW07 is too weak to robustly identify a centennial warm period during the MCA. During the first two centuries of the millennium, SGI presents a trough with a minimum around 1075 AD. This behaviour is also observed in the IPCC simulations forced by similar TSI variability, even when representing the effect of volcanic aerosols. During the same period Mob05 and M08 show a maximum around 1000 AD and a continuous decrease of the temperature until 1200 AD. This evolution is supported by the reconstructions overlap with good confidence.

Between 1200 and 1700 AD, the temperature in SGI decreases as in M08 and Mob05. The NH temperature of SGI shows common extremes with the reconstructions around 1400 and 1450 AD and with M08 and Mob05 around 1700 AD. The cold period identified as the LIA in SGI begins around 1400 AD as well as in the reconstructions, with a minimum around 1700 AD in SGI and M08. In Mob05 the temperature evolution shows a similar shape as SGI between 1400 and 1850 AD, but the minimum occurs around 1500 AD in Mob05. In AW07 the coldest period occurs after 1850 AD (not shown), two centuries later than in SGI, M08 and Mob05. The warming simulated by the model between 1750 and 1850 AD is stronger than in the reconstructions, potentially because of the missing impact of volcanoes. After 1400 AD, the NH temperature evolution in SGI is in better general agreement with the temperature reconstructions than before 1200 AD.

The industrial part of SGI warms strongly compared to the reconstructions and the IPCC and SW2010 simulations because of the missing volcanoes. We confirmed this hypothesis by running an additional simulation covering the 1850-2000 AD period (VHIST), starting from SGI in 1850 AD, with the volcanic forcing (not shown) used in the ENSEMBLE project (Royer et al., 2009). The resulting temperature evolution (Fig. 1c) is in better agreement with both reconstructions and IPCC simulations.

3.2 Forcing signature on NH temperature

For a critical assessment of the NH temperature variability in the preindustrial part of SGI we quantified the role of solar, CO₂ and orbital forcings on the NH temperature variability in the simulation. It implies evaluating the temperature variability due to internal processes and the part attributed to the forced variability. We hence used a statistical method based on a linear decomposition of the temperature anomalies 𝑑𝑇 as the sum of the first order contributions, or signatures, of external forcings 𝐸𝑖 and an associated residual noise 𝜖:

\[ dT = \sum_i \left( \frac{\partial T}{\partial E_i} \right) dE_i + \epsilon. \]

Following this decomposition we propose the following statistical linear model to describe the NH temperature anomalies in the simulation SGI (Fig. 3):

\[ T'(t) = C_1 \times TSI'(t) + C_2 \times [CO_2]'(t) + \epsilon(t), \]

with 𝑖 the time index, && TSI' and [CO₂]' the anomalies relative to the 1000–1850 period NH temperature, TSI and CO₂ concentrations respectively, \( C_1 = (\partial T' / \partial TSI) \) and \( C_2 = (\partial T' / \partial [CO_2]) \) the first order sensitivity of the model to TSI and CO₂ respectively, and \( \epsilon(t) \) the residual noise. The first step is to test the null hypothesis that only one forcing with an associated residual noise can explain the NH temperature variability. We estimated \( C_1 \) and \( C_2 \) with both univariate \((C_1^{UV} \text{ and } C_2^{UV})\) and bivariate \((C_1^{BV} \text{ and } C_2^{BV})\) linear regressions, following the nested regression models:

\[ T'(t) = C_1^{UV} \times TSI'(t) + \epsilon_1(t), \]

\[ T'(t) = C_2^{UV} \times [CO_2]'(t) + \epsilon_2(t), \]

\[ T'(t) = C_1^{BV} \times TSI'(t) + C_2^{BV} \times [CO_2]'(t) + \epsilon_3(t). \]

We calculated the signatures associated with TSI \( (S_{TSI}^{TSI}) = C_1^{UV} \times TSI'(t) \), CO₂ \( (S_{CO_2}^{CO_2}) = C_2^{UV} \times [CO_2]'(t) \), the total
residuals term in Eq. (3) represent 78% of the total variance of total forced variability in the simulation. The null hypothesis of a correlation \( r \) and the corresponding regression coefficients lie significantly (99.5% level) correlated to [CO\(_2\)] when the MCA (between 1000 and 1425 AD) and the second trend in temperature associated to changes in insolation due to orbital forcing dominates the NH temperature variability in the first part of the millennium (1425–1850 AD). The indices UV and BV denote the methods to estimate the coefficients, i.e. univariate and bivariate regressions, respectively. On the 1000–1850 period, the terms \( \varepsilon_3 \) and \( TSI' \) are equivalent to 82 and 79% of the total variance of \( T' \) and \( SGI \), with \( \varepsilon_3 \) corresponding to 79% of total variance, \( \varepsilon_3 \) is weak in front of the variance of the signature of CO\(_2\) concentration. This model also estimates that 13% of the total variance of \( T' \) is due to the joint contribution of TSI and CO\(_2\).

We repeated the analysis on the first part of the millennium covering the MCA. The estimates of \( C_{1BV} \) and \( C_{2BV} \) on the 1000–1425 AD time interval give a significantly greater value for \( C_{1BV} \) (0.13 °C/Wm\(^{-2}\)) and \( C_{2BV} \) is not significant (0.005 °C/ppm, p-value > 50). The correlation between TSI' and \( T' \) is 0.86, and 0.6 between [CO\(_2\)]' and \( T' \). The variance of the signature \( S_1^{(TSI)} \) corresponds to 79% of total variance, versus 88% for the total signature \( S_{tot} \). The variance of the signature of CO\(_2\) is weak in front of the variance of the signature of TSI, indicating that the null hypothesis represented by Eq. (1) is verified. This analysis clearly shows that solar forcing dominates the NH temperature variability in the first part of the simulation.

During the second part of the millennium (LIA), the variance of the signatures of the univariate models \( S_1^{(TSI)} \) and \( S_2^{(CO_2)} \) are equivalent to 82 and 79% of the total variance of

Table 1. Variances of the Northern Hemisphere temperature (\( T \)) in SGI and the signatures of solar (\( S_1 \)) and CO\(_2\) (\( S_2 \)) forcing estimated on the whole period, the first part (1000–1425 AD) and the second part of the millennium (1425–1850 AD). The indices UV and BV denote the methods to estimate the coefficients, i.e. univariate and bivariate regressions, respectively.

value ~ 0.01), confirming that orbital forcing can be neglected at hemispherical scale in annual average. The first order sensitivity of the NH temperature in the model to TSI variability and CO\(_2\) for the total preindustrial period estimated with bivariate linear regression is \( \varepsilon_3 \) = 0.10 °C/Wm\(^{-2}\) and \( \varepsilon_2 \) = 0.0022°C/ppm, respectively. The separated signatures of the bivariate model \( S_3^{(TSI)} \), \( S_3^{(CO_2)} \) and the residuals \( \varepsilon_3 \) explain respectively 45, 20 and 22% of the total variance.

The covariance term due to both solar and CO\(_2\) forcings (\( 2 \times \text{cov}(S_3^{(TSI)}, S_3^{(CO_2)}) \)) is equivalent to 13% of the total variance of \( T' \). The \( \varepsilon_3 \) residuals and the NH temperature anomalies of the CTRL simulation have similar variance and covariance. The bivariate model (3) is in very good visual agreement with SGI (Fig. 3), which gives good confidence on the robustness of the decomposition with the statistical model held by Eq. (3). We infer that on the whole 1000–1850 AD period the response of the model to the forcings dominates the NH temperature signal in the SGI simulation, and that the TSI variability has a stronger influence than the variations in CO\(_2\) concentration.

Value = 0.13 °C/Wm\(^{-2}\) is significantly greater than the value of 0.0022 °C/ppm which is not significant at the 0.05 level. The correlation between TSI' and \( T' \) is 0.86, and 0.6 between [CO\(_2\)]' and \( T' \). The variance of the signature \( S_3^{(TSI)} \) corresponds to 79% of total variance, versus 88% for the total signature \( S_{tot} \). The variance of the signature of CO\(_2\) is weak in front of the variance of the signature of TSI, indicating that the null hypothesis represented by Eq. (1) is verified. This analysis clearly shows that solar forcing dominates the NH temperature variability in the first part of the simulation.

During the second part of the millennium (LIA), the variance of the signatures of the univariate models \( S_1^{(TSI)} \) and \( S_2^{(CO_2)} \) are equivalent to 82 and 79% of the total variance of

Table 2. Sensitivity coefficients to solar (\( C_1 \)) and CO\(_2\) (\( C_2 \)) estimated on the Northern Hemisphere temperature in SGI, on the whole preindustrial period, the MCA and the LIA. The indices UV and BV denote the methods to estimate the coefficients, i.e. univariate and bivariate regressions, respectively.

Fig. 3. (a) Surface temperature anomalies relative to 1000–1850 AD reference period averaged over the Northern Hemisphere in SGI, on annual mean (grey line). The thick black line is the ten-year running mean applied on the annual averages, sampled every ten years to keep the number of degrees of freedom. The same treatment is done on the CTRL simulation, drawn on grey blue. (b) Fingerprints of solar (red lines) and CO₂ blue lines) forcings, estimated with univariate (dashed lines) and bivariate linear regressions and anomalies of TSI and CO₂ concentrations relative to the 1000–1850 AD period. The fingerprint of both solar and CO₂ forcings together is represented by the dark red line. The black thin line shows the 10 yr-running mean of the NH temperature of SGI presented on panel (a). (c) Fingerprint of both solar and CO₂ forcings together (dark red line). The residuals corresponding to SGI minus total forced fingerprint are represented by the green line. The light shaded area shows the interval corresponding to 1 standard deviation (SD) of the residuals, and the dark shaded area depicts the ±2SD of the residuals. The black line plotted over is the ten-year NH temperature of SGI presented on panel (a).

$T'$ respectively. Both $S_1(TSI)$ and $S_3(CO₂)$ are less correlated to $T'$ than on the whole preindustrial period (0.52 for TSI and 0.49 for CO₂) because they vary in opposite direction between 1450 and 1700 AD and are significantly detected during the LIA. The solar forcing signal is detected with a significant $C_{1UV}$ coefficient in $ε_2$ as well as the CO₂ signal in $ε_1$. The null hypothesis of either model (1) or model (2) is rejected. The estimates of $C_{1BV}$ and $C_{2BV}$ give $S_3(TSI)$, $S_3(CO₂)$ and $S_{tot}$ terms that correspond to 39, 36 and 61% of total variance, with a negative covariance term equivalent to 13% of $T'$ total variance. The correlation between the total fingerprint $S_{tot}$ and $T'$ is 0.78. This confirms that solar and CO₂ together explain the NH temperature variability in SGI during the LIA better than one forcing at a time. The variance of the residuals $ε_3$ corresponds to 38% of the total variance of $T'$. The decomposition of $T'$ with the bivariate model (Eq. (3)) between 1425 and 1850 AD attributes a lower part of the temperature variability to the external forcings than on the whole preindustrial period or the first part of the millennium.

To complete this analysis, we have computed the bivariate linear regression between $T'$ and both forcings taking into account a lag to catch a possible memory of the climate system. The coefficients obtained (not shown) show maximum values when the forcings precede the temperature by one to three decades, highlighting a memory effect likely attributable to the heat capacity of the oceans. However, the maximum coefficients lie in the confidence interval of the first estimate of $C_{1BV}$ and $C_{2BV}$. Taking into account a memory parameter in the statistical model held by Eq. (3) would not change dramatically the part of the total variance attributable to solar or GHG forcing.

The NH temperature in the SGI simulation shows a variance close to NH temperature reconstructions and IPCC simulations achieved with comparable secular forcings. The response of the model to the forcings on the whole preindustrial period is mainly linear. The LIA is driven at first order by both TSI and CO₂ and the minimum around 1700 AD is similar to the minimum identified in reconstructions. The evolution of the temperature during the first part of the millennium.
millennium, at ~80% linearly driven by solar forcing in SGI, appears to be different from the reconstructions, with the warmer period occurring two centuries later than in most of the records.

4 Multiscale signature of the forced variability

We have seen in the previous section that the Northern Hemisphere temperature in the SGI simulation is driven at 78% by the model response to the forcings, mostly represented by TSI variability. We now check whether this can be transposed to small geographical scales. The relative importance of forced and internal variability in a temperature signal depends on the radiative perturbation imposed as well as the influence of internal processes on the considered area. Ocean-atmosphere dynamics such as the El Niño Southern Oscillation (ENSO) in the Pacific Ocean or the North Atlantic Oscillation (NAO) over the North Atlantic sector are sources of important temperature variations that can be detected at the hemispherical or continental scale, while local processes involving meteorological phenomenon mix the signature of global forcings with a noise inherent to the climate system. All those internal processes are more or less independent, and their influence on the signal tends to vanish when averaging the temperature over large extents. In this section we assess the response of the IPSLCM4 climate model to solar, GHG and orbital forcings at spatial scales ranging from the globe to the individual cells of the model grid.

The next analysis estimates the characteristic spatial scale under which the temperature variance of our forced simulation SGI is comparable to the corresponding variance of the CTRL run, i.e. the model internal variability. We propose an estimate of the ratio between the variance of the temperature in SGI and in the CTRL as a function of the spatial scale considered, based on the additivity of the variance. We split the surface of the globe in $N$ areas, and compute the temperature time series averaged over those $N$ areas for both the SGI and the CTRL simulations. We then estimate a signal-noise ratio (SNR hereafter) defined as the ratio between the sum of the variances of the $N$ temperature time series in the SGI simulation and the sum of the variances of the corresponding time series in the CTRL, weighted by the root mean square of their associated areas, for the $s$ step needed to cut the globe in individual grid point with the cutting algorithm:

$$
\text{SNR}(s) = \frac{\sum_{i}^{N}(s) \text{var}(T_{\text{SGI},i}) \times \alpha_i}{\sum_{i}^{N}(s) \text{var}(T_{\text{CTRL},i}) \times \alpha_i}
$$

where $\alpha_i$ is the surface of the $i$th area on which the temperature time series of SGI $T_{\text{SGI},i}$ is averaged, and $\text{var}(T_{\text{SGI},i})$ the associated variance. The variance of the numerator is
considered as significantly different from the variance of the
denominator when the SNR is greater than the 99th quantile
of the Fisher distribution with a number of degrees of free-
dom equivalents to the number of degrees of freedom (Von
Storch and Zwiers, 2001) of the time series. The cutting al-
gorithm is illustrated in Fig. 4. The first estimate of the SNR
is done with the global mean \( N(s=1) = 1 \). We then split the
Earth by the equator for the second estimate \( N(s=2) = 2 \). The
hemispheres are then separated in two parts for the third step
\( N(s=3) = 4 \). The following steps consist in splitting every
area of the previous step by the middle of its sides to obtain
the next four zones \( N(s=i) = 4 \times N(s=i-1) \), until reaching
the grid point. The spatial scale of a given step is calculated
by computing the average of the extents of all the sectors.
We estimate the SNR with time series smoothed with eleven-
year, thirty one-year and fifty one year running mean to test
the sensitivity of the ratio to the frequency of the variabil-
ity considered. The results are shown in Fig. 5. The SNR
is maximum at global scale and minimum at the grid point
scale. It is high at the hemispherical scale as inferred from
previous section. It shows a continuous decrease and reaches
the significance threshold between 3 and 7.10^6 km^2, for all
the smoothing applied on the time series. The slopes of the
SNR curves are too low around the significance level to deter-
mine the dependence between the characteristic spatial scale
and the frequency of the variability (smoothing) considered.
For a given spatial scale, the SNR is higher with the lower
frequency time series because of the frequency of the forc-
ings imposed. The characteristic spatial scale of detectabil-
ity of the forced signal is 5.10^6 km^2, between the extent of
Australia and Europe.

Fig. 6. First order sensitivity of the temperature in SGI to TSI variability estimated by \( C_1^{BV} \) expressed in °C/Wm\(^{-2}\) (a, b, c), to \( \text{CO}_2 \) by \( C_2^{BV} \) expressed in °C/ppm (d, e, f), and slope of the \( \varepsilon_3 \) residuals corresponding to \( C_3 \) expressed in °C/1000 yr (g, h, i). Those coefficients are calculated for annual (a, d, g), summer (b, e, h, June-July- August) and winter (c, f, i, December-January-February) averages. The white areas represent the grid points where the coefficients are not significant at 99.5% (Student t test).

This first approach invites us to go deeper in the details of
the sensitivity of the model in SGI around the Globe. The
next step is to assess the local sensitivity of the model to
solar, GHGs and orbital forcings. For every model grid point,
we apply the statistical decomposition (3) used to describe
the NH temperature in the previous section, and add a term
corresponding to the influence of orbital forcing:

\[
T'(t) = C_1 \times \text{TSI}'(t) + C_2 \times [\text{CO}_2]'(t) + C_3 \times +t + \varepsilon_4
\]

with \( C_3 \) the slope of the \( \varepsilon_3 \) residuals, attributed to the linear
changes in insolation, and \( \varepsilon_4 \) the residual noise of Eq. (5).
The decomposition is done on annual, winter (December-
January-February, DJF hereafter) and summer mean (June-
July-August, JJA hereafter) on series smoothed with an

www.clim-past.net/6/445/2010/
Fig. 7. Percentage of temperature variance explained at first order by the terms in Eq. (4) corresponding to the fingerprints of solar (d, e, f), CO\textsubscript{2} (g, h, i), and orbital (j, k, l) forcings, and of all the forcings together (m, n, o). The white areas depicts the grid points where the fingerprints explain less than 5% of the total variance of the temperature at the given grid points, or where the regression coefficients shown on Fig. 5 are not significant at 99.5%. The upper panels (a, b, c) show the temperature variance of the ten-year smoothed time series used in this study. All those diagnostics are done on annual (a, d, g, j, m), summer (b, e, h, k, n) and winter averages (c, f, i, l, o).

Additionally we evaluated the percentage of the total variance of temperature at every grid point associated to the signatures of the forcings in Eq. (4) (Fig. 7), as done in Sect. 3 for the NH temperature. The white areas in Fig. (6) represent the grid points where the regression coefficients are not significant and the white areas in Fig. (7) show where the variance of the signatures explain less than 5% of the total variance at the grid point. This means that the temperature variability is dominated by internal processes or that the temperature variance is mainly explained by another forcing.

The sensitivity patterns (Fig. 6) associated with TSI and CO\textsubscript{2} show the highest values in the Polar Regions. This is likely due to the albedo feedback associated with sea-ice, especially in the Northern Hemisphere. The differences in sensitivity to TSI and CO\textsubscript{2} between JJA and DJF can be partly
explained by the latitude-months forcing patterns associated with variations in TSI and CO\textsubscript{2}, as illustrated in (Govindasamy et al., 2003) and (Dufresne et al., 2005).

The sensitivity to TSI (C\textsubscript{1}) is important in the tropics (∼0.2°C/Wm\textsuperscript{-2}) and of comparable amplitude on annual, summer and winter averages likely because the solar radiative forcing is almost constant with the seasons in this region. In the Northern high latitudes, the model sensitivity to solar forcing shows strong differences between summer and winter, reflecting the seasonal dependence of solar forcing with the latitude.

The sensitivity to CO\textsubscript{2} shows less contrasted patterns between summer and winter in high latitudes than sensitivity to TSI variations. This is consistent with the weaker seasonal cycle of the CO\textsubscript{2} radiative forcing in the Arctic region.

In the Southern Hemisphere the ocean-atmosphere-sea-ice dynamics around Antarctica generate important decadal to multi-decadal variability and the significant coefficients are restricted to small areas.

The slope C\textsubscript{3} shows the higher values in the Northern Hemisphere during summer and the highest values in the Arctic. On annual and winter mean the C\textsubscript{3} values do not show any latitudinal coherence, denoting that those trends are probably not linked to orbital forcing.

The temperature variance in SGI (Fig. 7) is the strongest in the high latitudes as well as the sensitivity to TSI, CO\textsubscript{2} and orbital forcing. The amount of variance explained by the signature of solar forcing in SGI is not strictly following the values of sensitivity to TSI variability. The temperature variance in the equatorial band is particularly affected by solar forcing because solar irradiance is high around the equator. The signature of TSI explains more than 50% of the temperature variance in the Western Pacific Ocean (Warm Pool), the Indian Ocean and the Equatorial Atlantic Ocean. It has lower impact in the Arctic despite higher sensitivity values. It explains more than 10% of the temperature variance over most of the continents on annual average, in North and South America, Africa, and Southern Asia. It is weakly significant over Europe on annual average and winter, and the variance of its signature can reach 25% of temperature variance in summer. At mid-latitudes, the variance explained by solar forcing in winter and summer follows the associated sensitivity patterns.

The signature pattern of CO\textsubscript{2} follows the C\textsubscript{2} sensitivity pattern. It reaches ∼25% of the temperature variance in the Polar Regions and Europe on annual averages and ∼25% of the temperature variance over Eastern Asia on summer averages. It shows a weak signature in the tropical area (∼10% of the temperature variance).

The higher values of the variance of the signature of orbital forcing follow the strong values of the C\textsubscript{3} coefficient, and occur during summer in North Africa and in the Arctic region. This behaviour reflects the latitudes where the orbital forcing has the biggest amplitude since the changes in the orbital parameters modulate essentially the solar input in the Polar regions during their respective summer.

We have compared the temperature of the SGI simulation to the summer temperature reconstruction over Arctic (>65° N) of Kaufman et al. (2009) (K09 hereafter). They found that their temperature record was following a linear decrease that they attributed to changes in insolation due to the precession of the equinoxes during the last two millennia. We calculated the annual and summer temperature above 65° N in SGI (Y\textsubscript{65} and S\textsubscript{65}), and applied the same smoothing as in K09. We also removed the linear contributions of TSI and CO\textsubscript{2} from the two time series calculated in SGI to focus on the signal due to orbital forcing C\textsubscript{3} × t (Y\textsubscript{65}ε\textsubscript{3} and S\textsubscript{65}ε\textsubscript{3}). Finally we estimated the slope of each time

Fig. 8. Comparison between the Arctic summer temperature reconstruction provided by (Kaufman et al., 2009) (grey and black lines) and SGI. The orange and red lines show the summer mean in SGI. The blue lines show the residuals calculated as the summer temperature time series in SGI minus the signatures of TSI and CO\textsubscript{2} (equivalent to the ε\textsubscript{3} residuals in Eq. 3). The grey, orange and light blue thin lines represent the ten-year smoothed time series of (Kaufman et al., 2009), SGI summer mean and SGI summer residuals, respectively. The thick black, red and blue lines show the linear regressions associated with the summer temperature time series of (Kaufman et al., 2009), SGI summer mean and SGI residual, respectively.
The total forced signal (Fig. 9) on annual and summer average on ~70% of the globe. On annual average, ~10% of the surface of the Earth is largely dominated by the total forced signal (>80% of the total temperature variance), in a similar proportion than the NH temperature of SGI.

We found that the characteristic spatial scale to detect a forced temperature signal significantly different from internal variability is ~5.10^6 km^2. The sensitivity to TSI and CO_2 is the highest in the polar regions, especially in the Arctic. The solar forcing explains ~50% of the temperature variance in the tropics. Its signature is dominant compared to CO_2 in both spatial extent and amplitude. Orbital forcing has a significant signature in the Arctic summer temperature and supports the conclusion of K09. Half of the temperature variance is explained at first order by forced variability on ~30% of the Earth’s surface.

5 Discussion and conclusion

We have performed two millennium-long simulations with the IPSLCM4 climate model to evaluate the impact of Total Solar Irradiance variability, CO_2 and orbital forcing on temperature during the last millennium. The SGI (Solar, Greenhouse gas and Insolation) simulation reproduces well the temperature evolution during the last millennium around the LIA. The amplitude of the NH temperature secular variability is in agreement with both temperature reconstructions and previous simulations (IPCC AR4 and SW2010) using similar solar and CO_2 forcings but taking into account the impact of the volcanoes. We found an important difference between the reconstructions and SGI between 1000 and 1200 AD, which also appears in the IPCC AR4 simulations.

We applied a linear statistical decomposition of the NH temperature before 1850 AD to evaluate the contribution at first order of the three forcings used on temperature variability at hemispherical scale. This decomposition demonstrated good skill at reproducing the NH temperature variability of the SGI simulation. We found that 80% of the NH temperature variance is attributed to the forced variability, dominated by solar forcing. The first part of the millennium showing the MCA in the simulation is driven only by TSI variability.

Fig. 9. Percentage of Earth surface (on x-axis) where the variances of the signatures of the forcings used in SGI explain at least the percentage of temperature variance represented on y-axis. This diagnostic is represented for solar (red line), CO_2 (blue line) and orbital (orange line) forcing and for all the forcings together (black line). The horizontal dashed lines underline 25 and 50% of temperature variance.
On the second part of the simulation (after 1425 AD), CO₂ and TSI explained equivalent proportion of NH temperature variance. This result shows a similar implication of CO₂ on temperature variations during the LIA as found by (Hegerl et al., 2007).

The mismatch during the beginning of the millennium is potentially due to uncertainties on the initial state of the ocean and uncertainties in the reconstructions. Nevertheless, we can have a critical view on the experimental setup. The mismatch implies that the secular variability of the NH temperature reconstructions during the MCA is not explained by the response of the model, mainly linear, to the TSI reconstruction. The use of a TSI reconstruction presenting lower amplitude will decrease the difference between reconstructions and simulations during this period, but will also weaken the temperature decrease between the MCA and the LIA. Lower amplitude of the secular temperature variability would be in better agreement with NH temperature reconstructions as AW07.

The IPCC AR4 and SW2010 simulations taking into account the impact of the volcanoes show secular NH temperature evolution very similar to SGI. Volcanic forcing seems to have a weak impact on secular NH temperature variability compared to the solar forcing used in SGI and IPCC AR4 simulations shown, i.e. with a TSI mean value during the Maunder Minimum 0.25% lower than modern value. With lower amplitude of TSI variability, the influence of cumulative eruptions on secular temperature variability would be different (Ammann et al., 2007; Gao et al., 2009; Hegerl et al., 2007).

We evaluated the significance of a variance ratio between the SGI simulation and the CTRL simulation with an estimate of a signal-noise ratio dependant on the spatial scale considered. We found that the temperature signal of the forced simulation SGI is significantly (99% level) different from internal variability for area wider than ∼5.10⁶ km², i.e. an extent equivalent to Europe. This characteristic spatial scale is suitable for the TSI, CO₂ and orbital forcings used in SGI and for this spatial resolution of IPSLCM4. The solar forcing had the most extended spatial signature on local temperature, and explained the most important part of temperature variance. Polar Regions are the most sensitive areas to the three forcings. The temperature variance in the equatorial band is the most affected zone by forced variability, essentially because of solar forcing. Orbital forcing is detected over 65° N in summer, which support the conclusions of (Kaufman et al., 2009). We found that the signature of the total forced variability was greater than 10% almost everywhere over land, but the total forced variability represent at least half of the temperature signal on only ∼30% of the surface of the globe.

The study of the SNR and local signatures of the forcings suggests that individual temperature reconstructions taken from random location around the globe are weakly affected by the linear response of the temperature to the forcings. It is necessary to reconstruct temperature during the last millennium over sufficiently large spatial extent to capture a temperature signal significantly affected by the forcings. The proxies used to reconstruct the temperature like tree rings, pollens or lake sediments are sensitive to the summer season when the temperature signal is the most affected by the forcings in SGI. This study highlights areas where the temperature variance is dominated by the forced signal. It will be extended to other climatic simulations on the last millennium taking into account a reconstruction of the optical depth of volcanic aerosols (Gao et al., 2009) with IPSLCM4 and a simulation performed with another coupled GCM (SW2010). A next step will consist of using a coupled GCM with a finer vertical resolution in the stratosphere and interactive ozone chemistry (Shindell et al., 2001; Meehl et al., 2009) allowing a dynamical response of the model to solar forcing.

Our study shows that the role of solar variability on secular temperature evolution during the last millennium is still not fully understood, especially during the MCA. There is a need for more complete spatial coverage of proxy records, focused on strategic locations where the signal of external forcing should be important compared to internal variability.
