Introduction

The monsoons are seasonal wind reversals that occur generally over the tropics and are associated with precipitation changes. These reversals correspond to opposite summer and winter temperature gradients between continent and ocean and between both hemispheres. They lead to dry winters and wet summers. The Australian monsoon system is part of the Asian monsoon, but because it is not in the same hemisphere as Asia, the dry (wet) Australian winter (summer) monsoon is synchronous with the wet (dry) summer (winter) Asian monsoon. Although a link between both monsoon systems is apparent in modern climates (Trenberth et al., 2000), this relationship has not yet been well defined for past climates (Williams et al., 2009; Wang et al., 2005). The past dynamics of the Australian summer monsoon have been estimated through pollen analysis (Williams et al., 2009; Wang et al., 2005; Moss and Kershaw, 2000; Kershaw, 1974; Kershaw et al., 2007; van der Kaars et al., 2006; van der Kaars and Dam, 1995). However, the past intensity of the Australian winter monsoon is more difficult to estimate using palynological techniques because it is mostly characterized by wind intensity. The Banda Sea is located north of Australia and experiences strong seasonal changes in its primary productivity (Moore et al., 2003). Coccolithophores are good markers of paleoproductivity (Beaufort et al., 1997). Here, we investigate the past variability of the Australian winter monsoon using coccolithophore analysis, and compare the results with a pollen-based reconstruction of summer monsoon humidity changes from the same core. The aim is to produce past
estimates of the dynamics of the Australian monsoon in both seasons and to compare the findings with the dynamics of the Asian monsoon system.

2 Regional setting

The climate over the eastern Banda Sea is dominated by the monsoon. During the austral winter (JJA), strong trade winds blow from the south-east. At the Equator, these south-east monsoon winds turn clockwise, blowing from the south-west towards southern Asia to form the South Asian Summer Monsoon (Fig. 1). In the Banda Sea, these austral winter winds produce an intense upwelling activity by Ekman pumping (Moore et al., 2003). Primary production (PP) reaches its peak between June and September, as shown by the monthly averaged, 1997–2010 SeaWif and MODIS remote sensing estimates of chlorophyll concentration between 4 and 5°S and 133 and 134°E (Fig. 2).

During the austral summer (DJF), the north-west monsoon brings moisture from the Indonesian archipelago and the Indian Ocean to Northern Australia. The strong atmospheric convection related to the southward migration of the Inter-Tropical Convergence Zone (ITCZ) induces high precipitation over the Banda Sea, the Arafura shelf and Northern Australia. During that season, oligotrophic conditions prevail in the western Banda Sea (Fig. 2).

Satellite chlorophyll data reveal not only a strong seasonal contrast in productivity but also a large inter-annual variability (Fig. 2). The yearly-averaged primary production burst was strongly limited during the 1998 La Niña year (Moore et al., 2003), with an average chlorophyll concentration of 0.28 mg m⁻³, a level which is significantly reduced from that of the 0.41 mg m⁻³ yearly average. In contrast, during the 1997 El Niño year, the high PP season lasted until November when concentrations remained as high as 0.31 mg m⁻³.

Fig. 1. Left: Map showing the mean wind fields (arrows) and geopotential height (m) for 925 hPa from NCEP-1 for June, July and August between 1949 and 2009. Right: Map showing the location of core MD98-2175.

Fig. 2. (a) Satellite imagery estimates of monthly Chlorophyll a concentration in mg per cubic meter (left) from MODIS averaged on 5–6°S and 133–134°E from 1997 to 2009. In blue for years 1998, 1999, 2000 and 2007 (La Niña’s), in red for years 2002, 2006 1997 and 2009 red dotted line) (El Niño events). Composites of JJA daily values (low-pass filtered) of a wind index (b: total; c: zonal; d: meridional speed) computed from NCEP-I averaged on 130°-135°E, 7.5°S–2.5°S at 925 hPa and for 10 El Niño (red) and 10 La Niña (blue) years selected from Niño 3.4 data averaged on JJA. The JJA value of meridional winds are correlated at 0.54 with Niño 3.4 on 1948-2009 at −0.07 for zonal component and 0.31 for speed.
(compared with usual levels of about 0.18 mg m\(^{-3}\)). Moore et al. (2003) concluded that the El Niño Southern Oscillation (ENSO) largely controls the inter-annual primary production dynamics. Estimates of chlorophyll a concentrations in the quadrilateral 5°–6° S/133°–134° E from 1997 to 2009 from MODIS remote sensing, indicate that, during El Niño years, the high PP season lasts longer and is more productive. This is consistent with the inter-annual wind variability estimated from NCEP-1 (National Center for Environmental Prediction) reanalysis, which shows that during El Niño years the strong wind season lasts about one month longer than in La Niña years (Fig. 2). However, during El Niño years the relative increase in PP is larger than that in wind intensity. This results from the change in the direction of the wind during El Niño events (more southerly), that changes the local divergence of surface winds (or curl of the wind), and enhances Ekman pumping during these events and therefore stronger upwelling. An increase in PP during El Niño years is contrary to the pattern observed in the eastern Pacific upwelling system (e.g. Philander, 1983). The fact that PP in the eastern Banda Sea reacts strongly to ENSO dynamics is to be expected because the Southern Oscillation Index is identified as the pressure difference between Tahiti and Darwin, in the area just south of the eastern Banda Sea (Bjerkness, 1969). Primary productivity is tightly coupled to wind stress, which controls upwelling formation and intensity. Thus, reconstructing of paleo-PP would make it possible to estimate long term variations in the Australian and Indonesian winter monsoon system. The length of the dry season is also related to ENSO; during El Niño events, northern Australia experiences longer dry seasons (although more intense rain in the wet seasons than during normal years) (Tuschetto et al., 2009).

3 Material and methods

3.1 Recovery and age control of core MD98-2175

Core MD98-2175 was retrieved by the RV Marion-Dufresne during the IMAGES IV cruise, in the eastern Banda Sea (5°00′16′′ S–133°26′76″ E) at a water depth of 2382 m, on a relatively flat plateau located on the north eastern slopes of the Kei Islands (Fig. 1). This plateau is separated by deep sea trenches from Irian Jaya to the north and the Arafura Shelf (and Aru Islands) to the east. The Kei Islands are relatively small, and do not possess large rivers. Thus, fluvial deposits and turbidites are limited in the core. The sediment consists of homogeneous fine olive grey clays rich in calcareous nanofossils.

The oxygen isotopic composition of the planktonic foraminifera *Globigerinoides ruber* was analysed at 10 cm intervals in the upper 20 m of the core and at 50 cm intervals between 20 and 31 m. Nine \(^{14}\)C dates were obtained on shallow dwelling planktonic foraminifera (*G. ruber* and a mixture of *G. ruber* and *Globigerinoides sacculifer* in 2 cases). Calendar ages were obtained by converting the \(^{14}\)C dates using IntCal09 (Reimer et al., 2009). We used a reservoir age of 515 years, which is an average of 6 reservoir ages from the northern Australian seas. For intervals that are beyond the limit for accurate \(^{14}\)C dating, the depth-age conversion is based on the correlation of the planktonic \(^{18}\)O record to the low-latitude oxygen isotope stack of Bassinot et al. (1994). Depth-to-age conversion was conducted through a linear interpolation between dated tie points (Fig. 3). Sedimentation rate is in the order of 47 cm per thousand years (cm.kyr\(^{-1}\)) in the upper 10 m of the core and 17 cm.kyr\(^{-1}\) between 10 and 35 m.

3.2 Coccolith analysis

Smear slides were prepared at a 5-cm interval in the upper 20 m of the core and at a 20-cm interval for the remainder
The coccolithophores are phytoplankton organisms that are widespread and abundant in the world’s oceans. Because they are photosynthetic organisms, they must remain within the photic zone, and most species are found within the upper 80 m of the water column. This part of the photic zone is often depleted in nutrients and the productivity is highest just above the nutricline. When the ocean is strongly stratified and the nutricline is too deep in the photic zone, the primary production is low. A few species (e.g. *Florisphaera profunda*, *Gladiolithus* spp. and *Algirosphaera* spp.) are adapted to low light environments and are commonly found between 80 and 180 m (Okada and Honjo, 1973). The relative abundance of *F. profunda* (the most abundant of the three deep living taxa) may serve to monitor the depth of the nutricline (Molfino and McIntyre, 1990). A high relative abundance of *F. profunda* indicates a deep nutricline and low productivity in shallow waters (and the reverse). The *F. profunda* index (%Fp) has been calibrated using data on the percentage of *F. profunda* (Fp) in a total of 400 counted coccoliths (total coccoliths = TC) in 96 core top samples from a large variety of environments in the Indian Ocean (Beaufort et al., 1997). This index (%Fp = 100×Fp/TC) was correlated to the estimated modern PP based on a compilation of 12-years of satellite observations with the Coastal Zone Colour Scanner (CZCS) (Antoine et al., 1995) to produce the simple transfer function: $PP = 617 - (279 \log \%Fp + 3)$.
(Beaufort et al., 1997). The use of F. profunda as an indicator of PP is now commonly used by nannopalaeontologists (e.g. Fernando et al., 2007; Incarbona et al., 2008; Liu et al., 2008; Lopez-Otalvaro et al., 2008). In core MD98-2175, the species belonging to the genera Gephyrocapsa, Emiliania and Florisphaera represent more than 90% of the coccolithophore assemblages. Thus, in core MD98-2175, the %Fp is calculated only using these taxa, as is proposed elsewhere (Flores et al., 2000). In doing so, there are minor differences compared with the use of the entire assemblage.

3.4 Analysis of pollen data

Quantitative reconstructions of austral summer rainfall and the number of dry months were derived from pollen data from core MD98-2175 (Kershaw et al., 2006; Kershaw and van der Kaars, 2007) using a newly developed set of transfer functions for palynological data from Indonesian waters. The functions were developed by one of us (SvdK) in the course of on-going work on modern pollen distribution in this region. The modern pollen distribution dataset used covers the Indian Ocean adjacent to northwestern Australia and southern Indonesia and contains 113 core-top samples collected during Australian (van der Kaars and De Deckker, 2003), Indonesian-Dutch (van der Kaars, 2001), and French-Indonesian SHIVA (1991) and BARAT (1994) cruises as well as cores collected in the Timor Sea by the German research vessel Sonne during the SO185 cruise. This present work follows the development of transfer functions that can be used both with terrestrial and marine Australian palynological records (Cook and van der Kaars, 2006; van der Kaars et al., 2006). Both transfer functions are based on percentage values of 116 common (occurring more than twice) tree and herbaceous taxa to produce the proxy climatic series. Leave-one-out cross validation of the climatic estimates yielded an \( r^2 \) of 0.65 for summer rainfall and 0.80 for the number of dry months. The dry months are those that receive less than 70 mm of rain (or less than the monthly value of the local temperature (in °C) multiplied by two). The pollen-based estimates were detrended by removing the first factor of a singular spectrum analysis (Vautard and Ghill, 1989) using the Analyserys software (Paillard et al., 1996). This detrending enabled extraction of the long term (>1/80 ky r⁻¹) variability leaving precessional type dynamics intact.

4 Results

4.1 Representation of %F. profunda

The core contained a generally abundant nannofossil assemblage (typically 10 to 30 coccoliths per field of view). The relative abundance of F. profunda varied between 25 and 73 percent, which is large in comparison with the reproducibility (Fig. 4). This range corresponds to a large changes of reconstructed primary productivity (varying between 92 and 214 gC.m⁻².yr⁻¹). Intervals of peak primary production are observed at 160, 135, 109, 87, 62, 43, 18 and 1 ka (Fig. 5a).

The average time interval between two adjacent productivity maxima is, therefore, ~23 ky r, clearly showing the importance of precessional forcing in the production dynamics of this area. The high sampling resolution and the small standard deviations make it possible to clearly reconstruct the symmetrical shape of primary production fluctuations. For instance, between 23 and 11 ka, the series contains 71 points having an average of 170 gC m⁻² yr⁻¹ (range = 150–203 and standard deviation = 40), well above the values found in the periods preceding and following.

The PP series has been resampled at a regular time interval of 1000 years. Time-series analysis (Blackman-Tukey and MTM), performed using the Analyserys software (Paillard et al., 1996), shows two main frequencies (Fig. 5e). The dominant frequency is at 23.3 kyr⁻¹, which corresponds to the main precession cycle (23.3 kyr r⁻¹). The second frequency corresponds to the obliquity cycle at 41.0 kyr⁻¹. Longer-term cycles, which could have been related to the global ice volume (i.e. ~100 kyr r⁻¹) are absent from this time series. Cross correlation (Blackman-Tukey) between the precession (in its standard definition of Param. $= e. \sin(\sigma)$ where $\sigma$ is the vernal point) and %FP indicates a phase of ~0.91 radian, equivalent to a phase-lock with an equatorial daily insolation for August 15th at a period of 23.4 kyr. At this periodicity, the coherency between %Fp and precession is 0.97, which is above a confidence level of 99.99% (0.91) for a bandwidth of 0.02. Because the chronology is based in the older part of the record (>50-ka) on δ¹⁸O tuning, implying lower chronological precision, it is reassuring that the phase of PP with precession appears to stay constant all along the record (e.g. Fig. 6b).

4.2 Rainfall levels and length of dry season as indicated by pollen transfer functions

In order to estimate past dynamics of the Australian monsoon, we concentrate on two palynological proxies: 1) the amount of summer rainfall as an index of the summer monsoon; and 2) the number of dry months, which should relate to the length of the winter monsoon. The long-term patterns are similar for the two proxies, with drier (wetter) summer conditions and longer (shorter) dry season during interglacials (glacials). The fact that a longer dry season corresponds to a wetter summer monsoon agrees with present inter-annual monsoon dynamics; El Niño years are characterized by a shorter and wetter summer monsoon season, and the dry season lasts longer (Moron et al., 2009, 2010; Taschetto et al., 2009). The long-term pattern follows the glacial/interglacial cycles with a ~100 yr periodicity (Fig. 5c, g). Shorter-term variations of the summer rainfall show a complex signal with 24 and 44 kyr periodicities that only show little significance (Fig. 5c, g). A 23-kyr cycle is not readily observed in the summer rainfall data but is clearly
visible in the number of dry months, and corresponds to a significant peak in the spectral analysis results (Fig. 5f). Once the time-series is detrended to remove long-term variations, the precessional pattern is seen even more clearly in the number of dry months time series (Fig. 5b).

### 4.3 Estimation of the length of the winter monsoon

Figure 5 shows the striking correspondence between the detrended series representing the number of dry months and the primary productivity series. It is also possible to estimate the length of the upwelling season from the PP estimates knowing the seasonal and interannual variability from
MODIS. As can be readily seen from Figure 2, the seasonality of the oceanic production in the Banda Sea is only based on two phases, one with a low monthly primary production (Pmin), and one with a high primary production (Pmax). Pmin is the base line of 0.2 mg Chlorophyl A m$^{-3}$, which is equivalent here to 8 gC m$^{-2}$ month$^{-1}$ (Antoine et al., 1997). Pmax depends on the yearly primary production (see Fig. 2) and here we have estimated the relationship between PP and Pmax as [Pmax = 0.12+0.15PP] using the El Niño, La Niña and mean curves (Fig. 2). It is possible to calculate the upwelling season length (USL) as a function of PP, Pmin and Pmax using the equation [USL = (PP-(12-Pmin))/Pmax-Pmin]. Note that Pmax-Pmin aims to reproduce the increase of PP when the winter monsoon is longer and more intense. With this model (equation) the length of the upwelling season and its intensity both contribute to the yearly primary production, and are converted into “upwelling season duration” (Fig. 6b). The anomalies (from record average) displayed in the length of the upwelling (derived from coccolithophores data) and dry seasons (estimated from palynological data) are in relatively good agreement (Fig. 6c). The amplitude of the precession signal is, however, often larger for the upwelling length anomalies than for the dry season length anomalies. This may be due to the fact that the upwelling season is longer (3 to 4 months) than the dry season (1–2 months). The two series were re-sampled at a resolution of 1000 years between 1 and 150 ka and then averaged. The resulting pattern is very similar to that in the Niño3 model of past ENSO variability proposed by Clement et al. (1999) (Fig. 6b). The correlation between this model and the average length of the winter monsoon season is $r=0.7$.

5 Discussion

5.1 Development of ENSO-like conditions

As seen above, reconstructions made using combined pollen and coccolith series from core MD98-2175 show that, in response to precessional forcing, the duration of the Australian winter monsoon has varied from $-0.6$ to $+0.3$ months. The significant correlations between the ENSO Niño3 model and the multiproxy estimate for the length of the winter monsoon, and equivalent fit in the modern climates (QuikSCAT and MODIS satellite data compared to Niño3) strongly support an interpretation that past ENSO dynamics form the basis of observed changes in the paleo-data from core MD98-2175. There is, however, a difficulty with such an interpretation. Using the Zebiak-Cane model (Zebiak and Cane, 1987), Clement et al. (1999) estimated that there would be at most (least) $\sim180$ ($\sim90$) warm events (El Niño) and $\sim150$ ($\sim50$) cold events (La Niña) per 500 years and that the amplitude in temperature of those events would not change dramatically (25%). This corresponds, using the estimated PP from satellite data (with 205, 141 and 175 gC m$^{-2}$ year$^{-1}$ for El Niño, La Niña and normal years) to a range of PP of 166 to 183 gC m$^{-2}$ year$^{-1}$. Those changes would not be sufficient to explain the large variations in the length and intensity of the winter monsoon exhibited by the pollen and coccolith data from the Banda Sea core and in its PP record which ranges from 90 to 213 gC m$^{-2}$ year$^{-1}$. It should be noted that, in other simulations of the same model, if the number of warm events is further diminished in the early Holocene,
the number of cold events is also diminished (Clement et al., 2000). In contrast, our data point to regular (every 23 kyr) more extreme shifts in ENSO with an amplitude similar to inter-annual climate variations observed since 1997. The ENSO system would be locked in a constant El Niño phase or in a constant La Niña phase, which is not physically possible. Some studies have indicated important weakening of El Niño in the middle/early Holocene (Rein et al., 2005; Moy et al., 2002; Rodbell et al., 1999) which agree well with our dataset, however, other studies have shown that ENSO cycles have been constantly present during the last 35 or 135 kyr (Grelaud et al., 2009; Tudhope et al., 2001, respectively). Both palaeo datasets and model results do not support a complete disappearance of El Niño in favor of La Niña over a long period of time. The atmospheric and oceanographic conditions that prevail during the two current opposite phases of ENSO may have been the mean states of low latitude climate during long periods of time and can be described instead as “ENSO-like”.

5.2 The monsoon in China and movement of the ITCZ

The speleothems from Hulu, Sanbao and Dongge caves, all located between 108 and 111°E and 25 and 32°N provide a very detailed record of the intensity of the summer monsoon in China from oxygen isotope measurements (Wang and Ding, 2008). As the Australian-Indonesian (austral) winter monsoon occurs at the same time as the (boreal) summer Asian monsoon, it is informative to compare the variability recorded in the MD98-2175 records with that of the Chinese speleothems. The composite Chinese speleothem δ18O record is dominated by precessional forcing and is in phase with the local mid-winter insolation (Wang and Ding, 2008). The same phase is found in the Banda Sea record. The phasing between the two records is stable during the last 150-kyr and therefore independent on the methodology used to built the chronology of the Banda Sea core (150-kyr and therefore independent on the methodology used to built the chronology of the Banda Sea core (14C or δ18O) (Fig. 6a, b and Fig. 7). The close resemblance between the two datasets appears clearly in Fig. 6a, b. This similarity suggests that the two monsoon systems are related, or at least are controlled by the same forcing mechanism. It is surprising that drier Chinese summer monsoon periods occurred at times of more intense winds in the Banda Sea and longer dry seasons.

Employing a simplistic model, it might be expected that the more intense Austral winter monsoon winds might have picked up a lot of water vapor from the ocean during their journey over Indonesia and South China Sea (and the Pacific) and delivered it into mainland Asia. Alternatively, the ITCZ might have migrated to a far northerly position during JJA causing a strong Asian monsoon, which would have corresponded to drier winter Australian monsoon conditions. However, these scenarios seem unlikely because the amount of rain received in China during the summer monsoon is not directly related to ENSO dynamics (e.g. Ropelewski and Halpert, 1987) or is related in a very complex way (Lau and Weng, 2001). We compared the recent relationship between the JJA meridional component of the wind in the western Banda Sea (124°–132°E, 8°S and Equator) and the rain anomaly in JJA for the period from 1979 to 2007 (Fig. 7). A drier area appears across the Australian-Indonesian region near the origin of the acceleration of the southerly winds; and wet anomalies appear above the Indo-Pacific warm pool (IPWP) probably due to the strengthened low-level convergence there. When the ITCZ is reinforced over the IPWP during the boreal summer, the rainfall tends to be anomalously low across most of mainland China. The patterns seen in present climates and the paleo-data each point toward a drier East Asian summer monsoon in China at times of stronger winter monsoon winds in the Banda Sea. Simple explanations based on spatially-homogeneous forcing linked to ENSO or ITCZ migration are therefore not necessarily valid here. We suggest that the observed evolution of the strength of the Australian and East Asian JJA monsoons depends on the evolution of the ocean/land thermal gradients related to the seasonal hemisphere path of insolation forced by precession. It could also be noted that the performance of current AGCM forced by prescribed SST to simulate inter-annual rainfall anomalies of boreal summer monsoon across China is rather poor (i.e. Li et al., 2010). This is associated with the fact that large-scale migrations of the ITCZ do

![Fig. 7. Correlation between June, July and August (JJA) meridional winds (124°–132°E, 8° S and Equator) and JJA rainfall in two datasets (CMAP = satellites + rain-gauges from 1979 to 2007). Despite the noise, different patterns are consistent to each other with weak (but significant) negative correlations over China (less rainfall when southerly winds increase). The dots indicate 90% significance level. Correlation between the rain and the meridional component of the wind (124°–132°E, 8°S and Equator) from 1979 and 2007. Position of the Hulu (H) and Sanbao (S) speleothem records and of MD98-2175 (MD) are also given in the map.](image-url)
probably not have a major role in driving interannual rainfall anomaly across China.

Simulations with the IPSL CM4 ocean-atmosphere coupled model on several orbital configurations show the influence of precession on monsoon and tropical climate (Braconnot et al., 2008). Our results show a very similar pattern. In those simulations, precession appears to largely control the response of the monsoon and induces large changes in the seasonal evolution of the Equatorial Pacific; each contributing to a large redistribution of energy. This feature is consistent with other simulations such as those made by Zheng et al., 2008, Cane et al., 2006, Clement et al., 1999, 2000.

5.3 Relationship between the Australian summer monsoon and other monsoon systems in the Holocene

The strong imprint of precession observed in the Banda Sea is a common feature of tropical climates (e.g. Pokras and Mix, 1987; Molfino and McIntyre, 1990; Beaufort et al., 1997; Schneider et al., 1997; Villanneva et al., 1998; Reichart et al., 1998). All of these have the same phase (beginning of August or February depending on the sign of the climate phenomenon), which is also observed in the Chinese speleothems and our Banda Sea records. Ruddiman (2006) proposed that the monsoon is in phase with summer insolation as models predict (e.g. Kutzbach, 1981). However, other monsoon records for which precession is not the dominant spectral feature, have a different phase in the precession band (often May or November) (Clemens and Prell, 2003; Clemens et al., 1991; Ziegler et al., 2010a). Because most of these latter records come from the Arabian Sea where the summer monsoon is well expressed, this late phase is usually accepted as the “monsoon phase”, and the records that display an early phase are considered as independent tropical climatic phenomena. Our findings, that all these records are responding to the same phenomenon, thereby explaining their synchronicity, are in agreement with Ruddiman, 2006; Reichart et al., 1998; Ziegler et al. 2010b; Braconnot et al., 2008; Wang et al., 2005, 2008; Zheng et al., 2008. It seems, therefore, that the “Global Monsoon” concept, which has been discussed for modern climates (Wang and Ding, 2008; Trenberth et al., 2000) is also valid for the paleo-variability of the tropical climates. Of course, the relevance of the Global Monsoon concept should be adapted to the type of paleoclimatic records considered (rainfall reconstructions across continents should be, for example, far noisier than wind reconstructions across oceanic domains); we simply stress here the synchronism between different regional monsoon systems. Because of the dominance of the precessional signal over obliquity and eccentricity (which are seen more in high latitude climates and are more representative of ice volume), variations in the past global monsoon system may have been relatively independent of ice volume variations. This is demonstrated by examining how the several sub-monsoon systems evolved during the Holocene when there were relatively small variations in ice-volume (Fig. 8). In the Banda Sea, the MD98-2175 record shows a strong shift in monsoon activity at about 6000 years. This shift is synchronous with an increase in aridity seen in the Sahel and Sahara in the mid Holocene in palaeo-records of the African monsoon from the western Atlantic Ocean (deMenocal et al., 2000). This mid Holocene change in the North African monsoon regime has been described in many studies (Servant and Servant-Vildary, 1980; Gasse and Van campo, 1994; Petit-Maire et al., 1997; Kropelin et al., 2008) and extends also to East Africa (see references in Gasse, 2000; Vincens et al., 2005). Mid-Holocene monsoon changes are also observed in the Arabian Sea area (Fleitmann et al., 2003; Fleitmann et al., 2007), the Tibetan Plateau (Gasse et al., 1991), and in Eastern Asia (Wang et al., 2008). Changes in ENSO dynamics are observed synchronously (Moy et al., 2002; Reif et al., 2005; Rodbell et al., 1999; Haug et al., 2001; Grelaud et al., 2009; Conroy et

Fig. 8. Dynamics of the monsoons in the Holocene: from top to base: Sea surface temperature anomaly (°C) in the eastern Atlantic ocean (deMenocal et al., 2000) in red, MD98-2175 record of primary production in black; insolation at the Equator in August (purple); Precession cycle stack of speleothem data from China (red) and anomaly in the length of the winter monsoon in months (black) (the two records were resample at 1000 year intervals, cut into seven segments covering each a precession cycle (starting at 0, 21, 46, 71 94 116 and 137 ka). The age at the beginning of each segment was subtracted to the entire time column so each segment starts at zero BP), finally the seven segments were stacked together by computing their average at any given time).

al., 2008). In the Holocene, the monsoon follows the same phase in the precession band as in the seven previous precession cycles (Fig. 8). Therefore, as suggested quite some time ago by Kutzbach (1981), it appears that changes in low-latitude summer insolation drive the dynamics of the monsoon, with a very short time lag. The Holocene data indicate that, because of the early response of the tropics to insolation forcing and the relatively delayed response of ice volume, changes in records from the tropical climates often precede global changes in δ18O records (Beaufort et al., 1997; Beaufort et al., 2001). This is also visible at the end of the penultimate interglacial in our records (Fig. 6c), where changes in pollen and coccolith data precede the changes of δ18O occurring at the beginning of Marine Isotopic Stage 5.4 (5d) by about 5000 years. It is therefore not possible to attribute large scale changes in tropical hydrological systems observed at precession time scales to the global variability of ice volume. Conversely, our data suggest that at the time when the Earth enters an ice-age, the tropics will have already held their present precession climate configuration for some few thousand years.

6 Conclusions

The dynamics of the Australian winter monsoon have been reconstructed using two different types of proxies in the Eastern Banda Sea. Primary production, the length of the winter monsoon, and the amount of rainfall during the summer were estimated for the last 150,000 years. The summer monsoon rainfall follows the glacial-interglacial dynamics, whereas the winter monsoon proxies (primary production and length of the dry season) are strongly influenced by precessional cycles. The austral winter monsoon dynamics are in phase with low latitude insolation in August. A synchrony with other regional monsoon systems and ENSO is found at precession time scales, pointing to common climatic forcing of the different regional systems. These latest observed changes in winter monsoonal variability in the low latitudes, already established for a few thousand years, form a pattern similar to that seen at the onset of the glaciations during MIS5, and indicate that tropical climates precede glaciations by a few thousand years.

Acknowledgements. We thank Noëlle Buchet for her technical assistance. Funds for this study were provided by the French Agence Nationale de la Recherche (ANR) program award number ANR-05 PICC, and from the European Community’s Seventh Framework Program under grant ENV.2009.1.1.1.1 “Past4Future”. The radiocarbon dating was supported by the Australian Institute of Nuclear Science and Engineering (AINSE) grant 06/183 to SvDK and LB. SvDK gratefully acknowledges the support of a Logan Research Fellowship from Monash University, and funding from The Australian Research Council (ARC). We thank Ellyn Cook for revision of the text and acknowledge the thoughtful comments made by Martin Ziegler and an anonymous reviewer which, all, greatly improved the manuscript.
